This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

+ *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.

+ *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.

+ *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.

+ *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at `http://books.google.com/`

PREFACE

TO

THE SIXTH EDITION.

SINCE the publication of the fifth edition of this DICTIONARY in 1860, many additions have been made to our knowledge, and some very important applications of Science have taken their place amongst the established manufactures of this and other countries. The beautiful series of Aniline Dyes have, since that date, been fully developed. Several other tinctorial agents have also, by the industry of chemists, been introduced and adopted by the manufacturer. The production of Paraffine Oils from the cannel coal and bituminous shales of the North Wales and other coal fields, may be regarded as almost a new industry. Machinery has been introduced to relieve man from the terrible labour of puddling iron, and in many Iron works is now in successful operation. The labour of "getting" coal, which is, under many conditions, of the most trying nature, has also been assisted by "Coal-cutting Machines" of great ingenuity, many of which are now used in our collieries. Attention has been forcibly directed to the importance of providing a means for determining the presence of, and the quantity accumulating in any part of a coal mine of, the destructive fire-damp. The "Fire-damp Indicator" has been invented, and it must be regarded as one of the most interesting of the applications of Science—as it promises to be one of the most valuable.

All these and many other equally important discoveries and inventions, will be found fully described in this edition. The articles on Artillery and Fire Arms have been rearranged, and much new matter added to them.

The utmost care has been taken to learn of any improvements in any of the Arts and Manufactures, or in the operations of Mining. The article on the Dressing of Ores has been rendered very complete; especial attention has been given to every variety of Mining machinery; and every change introduced, the value of which has been proved, will be, it is believed, found described in the following pages.

The experience gained since the publication of the last edition of this Dictionary, has taught me more thoroughly the requirements of

Digitized by Google

those who have adopted it as a general book of reference. In preparing, therefore, this edition, it has been thought desirable to include some sufficient notice of every material known to enter into any process of manufacture; and of some, which although not at present employed, appear likely to prove valuable within a short time. Some hundreds of articles are described in this, which were not noticed in the previous editions.

Beyond these few remarks it is only necessary to state that great care has been observed in correcting these volumes; the original articles having been, in nearly every case, submitted to the authors of them, and in many instances subjected to rearrangement. The latest authorities have been consulted on each subject, and thus, it is hoped, the most recent and the best information secured. No labour has therefore been spared to render the articles in these volumes strictly reliable and generally useful.

In concluding my labours, I have the satisfaction of feeling, whatever may be the verdict of the public as it regards the general merits of the Dictionary, that I have conscientiously sought to secure the means necessary for rendering it a useful work of reference to all who are concerned or interested in the ARTS, MANUFACTURES, or MINES.

ROBERT HUNT.

PREFACE

TO

THE FIFTH EDITION.

It may appear to those who are familiar with the former Editions of Dr. Andrew Ure's Dictionary of Arts, Manufactures, and Mines, that but few words are necessary for the Introduction to a new issue of a work which is so well known to the public. If the present Edition appeared under the ordinary circumstances of a reprint,—with modern discoveries, and new applications added,—little would have been required in the way of preface. Such, however, is not the case, for, although this Dictionary is based on, bears the name of, and is in style and intention similar to, the production by Dr. Ure, it cannot but be regarded, from the extent of original matter which has been introduced, as a new publication.

Dr. Andrew Ure's Dictionary of Arts, Manufactures, and Mines, has, during many years, occupied a very important position in, what may be termed, the Commercial Literature of England.

There were few men more familiar with the applications of Science, and the details of all those Arts and Manufactures which involved the discoveries of Chemistry, than the late Dr. Ure. Perhaps no man was more frequently consulted upon questions of patent right, or concerned in experiments which had for their objects the removal of difficulties in the processes which the laboratory had given to the manufactory. With these advantages, superadded to such as naturally belong to a comprehensive mind, trained with much industry in habits of close observation, it could scarcely be otherwise than that a work of a technological character produced by such a man should reach a high standard of excellence.

Many of the most eminent amongst the living men of science, look back with feelings of affection to the days when, commencing their studies, they were guided by the clear light shed upon their paths by Ure's *Dictionary of Chemistry*. This science, since the fourth Edition of that work (the Edition now before me) was published in 1831, has completely changed its character. One vast division — that of organic chemistry — having been indeed created within the thirty years which have elapsed, and the theory of chemical combination having been

Digitized by Google

established upon a more philosophic basis. Consequently the features of any new Edition of that work must present an entire change, and to the young chemist of the modern school the original must necessarily wear an unsatisfactory aspect. There is, however, one feature in connexion with the original Dictionary of Chemistry of Ure, which it is desirable to see repeated in all our modern works on that, or any other, branch of science. A peculiarly lucid style distinguished all the articles which proceeded from the pen of Dr. Ure in those days, and many of the essays, devoted to physico-chemical science, are worthy of preservation, as examples, from which writers on similar subjects might learn to reach that clearness of expression united with elegance of diction which distinguishes them, but which is exceedingly rare in this class of literature at present.

The *Dictionary of Chemistry* slid by degrees into the more comprehensive book, the *Dictionary of Arts, Manufactures, and Mines*, which became the original of several similar works in this country, in France, and in Germany. During the lifetime of Dr. Ure the latter book passed through four editions, all of which have been found to be eminently useful to the manufacturer, the man of business, and the student of technology. In consequence of an arrangement made with Messrs. Newton and Son, of Chancery Lane, we are enabled to retain much valuable matter extracted by Dr. Ure for his last edition from a Series of Essays first published in 'Newton's London Journal of Arts.' The extracts, relating in great part to novelties of an interesting and useful nature displayed in the Great Exhibition of the Industry of all Nations, will be found included under the following heads, viz.: Alum, Beer, Citric Acid, Clay, Envelopes, Glass, Knife-cleaning Machines, Matting, Meats Preserved, Nickel, Oxalic Acid, Paging Machines, Printing and Numbering Cards, Sand, Soap, Sulphuric Acid, Tartaric Acid, and White Lead.

A careful examination of this work, after the death of Dr. Ure, proved that the shackles of age had, to some extent, prevented his embracing all those applications of science which have been made with most rapid strides within the last few years. Consequently, the publishers, resolved to spare nothing which should contribute towards maintaining the usefulness of this work, committed it to my care, fully entertaining the view that competent writers should be engaged, to furnish articles on those special industries which they have made the subject of their particular study.

From an examination of the list of contributors it will be seen, that in many instances the highest authorities—men whose original investigations have contributed to support the dignity of British science—have written articles for the present Edition. Indeed, it has been my earnest endeavour to obtain, upon every branch in each of the three divisions of this Dictionary, the most efficient aid, and to gather information upon every subject, from the most reliable sources.

Digitized by Google

For the zealous and really kind manner in which assistance has been afforded I am bound to express my obligations. But for this friendly cooperation the task of producing the present work would have been infinitely more laborious than it has proved to be. To the living I can only use general terms of thanks, since any selection would be unjust, where all have shown so large an amount of earnestness.

Death has, however, removed from the list of our fellow labourers, while the printers have been engaged on this work, three friends to whose names a few words may be allowed, and to whose memory some tribute is due.

There was no one from whom I counted for more assistance in all that related to the applications of chemical science, than from Henry M. Witt. A few articles from the pen of that young chemist appear in these volumes, and had not his too sensitive mind given way under the unfortunate circumstances in which it had pleased Providence to place him, there can be no doubt but he would have achieved honours in the path he had chosen. T. H. Henry, whom we have also lost, and whose loss is deeply regretted, was a chemist of longer standing, and consequently better known — especially for the correctness of his analytical investigations, and his perfect knowledge of metallurgical chemistry. Herbert Mackworth, one of Her Majesty's Inspectors of Collieries, came to his early end, no doubt, from the zeal which led him, in the practice of his professional duties, into badly-ventilated mines. He was a man ever anxious to improve the condition of the working miner, and to relieve him, as far as possible, from those disastrous accidents which are so fatal to this industrious class. From him I obtained valuable assistance,—beyond that which is indicated by his initials,—on various points connected with engineering as applied to our subterranean operations.

A few words on the plan of the present work. As in the former editions, the mere handicrafts were not included, so in this, they have, unless where they possess more than ordinary interest, been omitted, as it was not possible without greatly extending the work to comprehend them.

The objects which have been steadily kept in view are the following:—To furnish a work of reference on all points connected with the subjects included in its design, which should be of the most reliable character. To give to the scientific student and the public the most exact details of those manufactures which involve the application of the discoveries of either physics or chemistry. To include so much of science as may render the philosophy of manufacture at once intelligible, and enable the technical man to appreciate the value of abstruse research. To include such commercial information as may guide the manufacturer, and fairly represent the history and the value of such Foreign and Colonial productions as are imported in the raw condition. To present to the public, without much elaboration, a sufficiently copious description of the Arts we cultivate, of the Manufactures for which we are distin-

Digitized by Google

guished, and of those Mining and metallurgical operations which are so preeminently of native growth, including at the same time a sufficiently detailed account of the industries of other states.

The greatest care has been taken to render all the cross-references as complete as possible, without putting the reader to the vexatious process of hunting to and fro amongst the pages, for the information for which he seeks. It is hoped that the Dictionary will be found to answer the great end of such a work, and that the facts in which it deals may be found with facility. For all those articles which have not initial letters indicating the authors' names, I am entirely responsible. Of these, a few have been reprinted without much alteration from the former edition; but by far the larger number have been written by me, after having obtained the fullest information from the best authorities. I have never hesitated to take fresh knowledge from any source, — but if I have omitted to acknowledge the source, the neglect is unintentional.

I commenced the New Edition of Ure's Dictionary with an earnest determination to render the work as complete and as correct as it was possible for me to make it. I soon became conscious of my imperfect knowledge of many subjects embraced within the scheme, — and even after having laboured to acquire that knowledge from books, I often found there was still a want. In my necessities I have asked the aid of the manufacturer, and the advice of the man of science — and never having been refused the information solicited, I am led to hope that those who may possess these volumes will find in them more practical knowledge than exists in any work of a similar character. For this they are indebted to the liberal feeling which marks the great manufacturers of England, and distinguishes her men of science. With these remarks my labours are committed to the public — trusting that their verdict will be, that I have used my abilities and my industry so as to produce a Dictionary of Arts, Manufactures, and Mines which will be found practically useful to all who are engaged in these special divisions of human industry, and prove valuable as a book of reference to every inquirer.

LIST OF THE CONTRIBUTORS.

General Editor.—ROBERT HUNT, F.R.S. F.S.S.

KEEPER OF MINING RECORDS, ETC.

W. C. AITKIN, Esq.
Birmingham.

G. ANSELL, Esq., Royal Mint.

H. K. BAMBER, Esq., F.C.S., &c.

H. BAUERMANN, Esq., F.G.S.
Author of the Catalogue of Mining Models, &c., Museum of Practical Geology.

E. W. BINNEY, Esq., F.G.S., &c.,
Manchester.

H. W. BONE, Esq.
Enameller.

HENRY. W. BRISTOW, Esq., F.G.S.
Author of *Glossary of Mineralogy*. Geological Survey of Great Britain.

R. J. COURTNEY, Esq.
Superintendent of Messrs. Spottiswoode and Co.'s Printing Office.

JAMES DAFFORNE, Esq.
Assistant Editor of the *Art Journal*.

JOHN DARLINGTON, Esq.
Mining Engineer, Author of *Miner's Handbook*.

(*The late*) F. W. FAIRHOLT, Esq.,
F.R.A.S., Author of *Costume in England, Dictionary of Terms in Art*, &c.

E. FRANKLAND, Esq., Ph.D., F.R.S.,
and C.S. Professor of Chemistry at Royal School of Mines, and Lecturer on Chemistry at the Royal Indian Military College, Addiscombe.

ALFRED FRYER, Esq.
Sugar Refiner, Manchester.

(*The late*) T. H. HENRY, Esq., F.R.S.
and C.S.

R. HERRING, Esq.
Author of *History of Paper Manufacture*.

JAMES HIGGINS, Esq.
Calico Printer, &c, Manchester.

W. HERAPATH, Esq., M.D., &c.

SAMUEL HOCKING, Esq., C.E.
Camborne, Cornwall.

RICHARD W. HUNT, Esq.
Brewer, Leeds.

T. B. JORDAN, Esq.
Engineer, Inventor of Wood Carving Machinery.

JAMES JORDAN, Esq.
Assistant in Mining Record Office, Museum of Practical Geology.

(*The late*) WILLIAM LINTON, Esq.
Artist, Author of *Ancient and Modern Colours*.

JAMES Mc ADAM, Jun., Esq.
Late Secretary of the Royal Society for the Cultivation of Flax in Ireland.

(*The late*) HERBERT MACKWORTH,
Esq., C.E., F.G.S., one of H.M. Inspectors of Coal Mines.

HENRY MARLES, Esq. L.R.C.P.
Author of *English Grammar*; *Currying and Leather*.

DAVID MORRIS, Esq., of Manchester.
Author of *Cottonopolis*, &c.

JAMES NAPIER, Esq., F.C.S.
Author of *Manual of Dyeing, Electro-Metallurgy, Ancient Works in Metal*, &c.

D. NAPIER, Esq., C.E. &c.

(*The late*) A NORMANDY, Esq., M.D.,
F.C.S. Author of *Handbook of Commercial Chemistry*.

HENRY M. NOAD, Esq., Ph.D., F.R.S.
Author of *A Manual of Electricity*, &c.

AUGST. B. NORTHCOTE, Esq., F.C.S.
Assistant Chemist, University of Oxford.

ROBERT OXLAND Esq., F.C.S.
One of the Authors of *Metals and their Alloys*.

THOMAS JOHN PEARSALL, Esq.,
F.C.S. Secretary to London Mechanics' Institution.

SEPTIMUS PIESSE, Esq
Author of *Treatise on Art of Perfumery*, &c.

JOHN ARTHUR PHILIPS, Esq.
Graduate of the Imperial School of Mines, Paris, Author of *Manual of Metallurgy*.

ANDREW CROMBIE RAMSAY, Esq.
F.R.S. and G.S., Professor of Geology, Government School of Mines, Local Director of the Geological Survey of Great Britain.

T. A. READWIN Esq., F.G.S.
Salford, Manchester.

(*The late*) EBENEZER ROGERS, C.E.,
F.G.S., late President of the South Wales Institute of Engineers.

F. W. RUDLER, Esq.
Assistant Curator, Museum of Practical Geology.

CHARLES SANDERSON, Esq., Sheffield, Author of Papers on *Steel and Iron*.

E. SCHUNK, Esq., Ph.D., F.R.S. and C.S.

R. ANGUS SMITH, Esq., Ph.D., F.R.S.
Author of various Papers on *Air and Water*, *Life of Dalton*, and *History of Atomic Theory*, &c.

WARINGTON W. SMYTH, Esq., M.A.,
F.R.S., and G.S., Professor of Mining and Mineralogy, Government School of Mines, and Inspector of Crown Mines.

THOMAS SOPWITH, Esq, C.E., F.R.S.,
and G.S., Author of *Isometrical Drawing*, &c.

(*The late*) ROBERT DUNDAS THOMSON, Esq., M.D., F.R.S. Professor of Chemistry in St. Thomas's Hospital College.

ALFRED TYLOR Esq., F.G.S.
Author of *Treatise on Metal Work*.

A. VOELCKER, Esq., Ph.D., F.C.S.
Professor of Chemistry, Agricultural College, Cirencester, and Consulting Chemist to the Royal Agricultural Society of England.

CHARLES V. WALKER, Esq., F.R.S.,
F.R.A.S., Engineer of Telegraphs and Time to the South Eastern Railway Company, Author of *Electrotype Manipulation*, Translator of *Kæmtz' Meteorology*, *De la Rive's Electricity*, &c.

C. GREVILLE WILLIAMS, Esq.
Author of *A Handbook of Chemical Manipulation*, &c.

WM. MATTIEU WILLIAMS, Esq.
Caergwrle, North Wales.

(*The late*) HENRY M. WITT, Esq, F.C.S.
Assistant Chemist, Government School of Mines.

With special assistance and information from the late Sir Wm. Reid. C.B., Governor of Malta; Sir Wm. Armstrong, C.E., &c.; Robert Mallet, Esq., C.E., F.R.S., &c.; Captain Drayson, Royal Artillery; George W. Lenox, Esq.; and many others.

Digitized by Google

A

DICTIONARY

OF

ARTS, MANUFACTURES, AND MINES.

A

ABA. A woollen stuff manufactured in Turkey.

ABACA. A species of fibre obtained in the Philippine Islands in abundance. Some authorities refer those fibres to the palm-tree known as the Abaca, or *Anisa textilis*. There seem, indeed, several well-known varieties of fibre under this name, some so fine that they are used in the most delicate and costly textures, mixed with fibres of the pine-apple, forming Pina muslins and textures equal to the best muslins of Bengal. Of the coarser fibres, mats, cordage, and sail-cloth are made. M. Duchesne states, that the well-known fibrous manufactures of Manilla have led to the manufacture of the fibres themselves, at Paris, into many articles of furniture and dress. Their brilliancy and strength give remarkable fitness for bonnets, tapestry, carpets, network, hammocks, &c. The only manufactured articles exported from the Philippine Islands, enumerated by Thomas de Comyn, Madrid, 1820 (transl. by Walton), besides a few tanned buffalo hides and skins, are 8000 to 12,000 pieces of light sail-cloth, and 200,000 lbs. of assorted abaca cordage.

ABIES (*in Botany*), the fir, a genus of trees which belong to the coniferous tribe. These trees are well known from their ornamental character, and for the valuable timber which they produce. They yield several resins or gum-resins, which are useful in the arts.

ABIES BALSAMEA (the Balm of Gilead fir) produces the Canadian balsam. This tree grows most abundantly in the colder regions of North America.

ABIES CANADENSIS (the hemlock spruce fir). A considerable quantity of the essence of spruce is extracted from the shoots of this tree; it is, however, also obtained from other varieties of the spruce fir. See SPRUCE ESSENCE.

ABIES PICEA of Linnæus (*Abies pectinata* of De Candole). The Silver fir, producing the Burgundy pitch and the Strasburg turpentine. See TURPENTINE.

ABIETINE. A pale yellow, transparent, viscid exudation from the *Abies pectinata*, a variety of the silver fir, growing in the neighbourhood of Strasburg, is commonly called Strasburg turpentine. It contains 35 per cent. of a volatile oil of an agreeable smell, combined with a resin, and a small quantity of the acid of amber, as well as the peculiar body called *abietin*, a resin of an acid kind, styled therefore by some abietic acid. If the ordinary resin be removed by absolute alcohol, and the remainder digested with carbonate of potash, an abietate of potash is obtained from which the crystalline *Abietine* can be procured. This peculiar substance dissolves in petroleum and crystallises out of it. Strasburg turpentine resembles Canadian balsam, and is used for attaching microscopic objects to glass slips.

ABLETTE, or ABLE, is a name given to several species of fish, but particularly to the Bleak, the scales of which are employed for making the *pearl essence* which is used in the manufacture of artificial pearls. See PEARLS, ARTIFICIAL.

ABRASION. The figuration of materials by wearing down the surface. In general, the abrasive tool or grinder is exactly a counterpart of the form to be produced; thus, for plane surfaces a flat grinder is employed, and for concave surfaces a convex grinder. GRINDSTONE; FILE.

ACACIA. (*L. acacia*, a thorn; Gr. ἀκή, a point.) The acacia is a very extensive genus of trees, or shrubby plants, inhabiting the tropical regions generally, but extending in some few instances into the temperate zone; being found, for example, in Australia and the neighbouring islands. Botanists are acquainted with nearly 300

Digitized by Google

species of the acacia, some of them yielding *gum arabic*, *catechu*, and other gums known in commerce; while others give a large quantity of *tannin*, especially a variety which grows in Van Diemen's Land or Tasmania. The *Acacia vera* is a native of Arabia and of Africa from Senegal to Egypt; the *A. Arabica* is found in the same countries and in India; the *A. Karoo* belongs to the Cape of Good Hope, producing the Cape gum; *A. Gummifera* is chiefly found in Africa near Mogadore; *A. Scyal* in Senegambia; *A. tortilis* grows in the Desert, as does also *A. Ehrenbergii*, their gums being collected by the Bedouin Arabs; and *A. senegal* grows in Arabia and Africa, from Senegal to the Cape of Good Hope. From these plants the different varieties of gum. See ARABIC, GUM; GUM.

ACACIA CATECHU. The catechu acacia (*Mimosa catechu* of Linnæus) is a tree with a moderately high and stout stem, growing in mountainous places in Bengal and Coromandel, and in other parts of Asia. Its unripe pods and wood, by decoction, yield the catechu, or *terra Japonica* of the shops. See CATECHU.

ACAJOU (BOIS D'). The French name for mahogany, *which see.*

ACESCENT. Substances which have a *tendency* to pass into an acid state; as an infusion of malt, &c.

ACETAL. ($C^{12}H^{14}O^4$.) One of the products of the oxidation of alcohol under the influence of oxygen condensed in platinum-black. Pieces of well-cleaned pumice-stone are moistened with nearly absolute alcohol, and placed at the bottom of a wide-mouthed flask, which is then filled with capsules containing platinum-black, and exposed to a temperature of 20° cent. (67° Fahr.) till the whole of the alcohol is acidified. It is a colourless, mobile, ethereal liquid, boiling at 221° F. Its density in the fluid state is 0·821 at 72°. The specific gravity of its vapour 4·138 *Stas.* (mean of three experiments): calculation gives 4·083 for four volumes of vapour.—For the description of the modes of determining vapour volume, see the article EQUIVALENTS, CHEMICAL.—The recent researches of Wurtz render it evident that the constitution of acetal is quite different to what has generally been supposed, and that it is in fact glycodiethyline; that is to say, glycole in which two equivalents of hydrogen are replaced by two equivalents of ethyle.—C. G. W.

ACETATE. (*Acétate*, Fr.; *Essigsaure*, Germ.) Any saline compound in which the acid constituent is acetic acid. All acetates are soluble in water: the least soluble being the acetates of tungsten, molybdenum, silver, and mercury. The acetates, especially those of lead and alumina, are of great importance in the arts. The acetates are all described under their respective bases;—a rule which will be adopted with all the acids. See ACID.

ACETIC ACID. (*Acide acétique*, Fr.; *Essigsaure*, Germ.; *Acidum aceticum*, Lat.; *Eisel*, Sax.) The word "acetic" is derived from the Latin *acetum*, applied to vinegar; probably the earliest known body possessing the sour taste and other properties which characterise acids; hence the term ACID, now become generic; both the Latin word and also the Saxon *acid* being from the root *acies* (Greek ἀκή), an edge or point, in reference to the *sharpness* of the taste.

Vinegar must have been known from the most remote periods of antiquity. It is mentioned by Moses.* Hippocrates employed it in medicine under the name ὄξος.† Hannibal, in his passage over the Alps, is said to have softened the rocks by fire and vinegar.‡ It was known to the alchemists in the more concentrated state in which it is obtained by the distillation of acetate of copper (verdigris); being mentioned both by Geber § and Stahl.

Crystallised acetic acid was first obtained by Westendorf ‖ and Lowitz.¶

Acetic acid exists in nature only in the organised kingdoms, or as a product of the oxidation of organic bodies. According to Vauquelin and Morin it is found in the juices of certain plants, and it probably exists in certain animal fluids.

Gmelin and Geiger state that it has been found in mineral waters, which is quite possible, having been derived from the decay of organic matter originally present.

Acetic acid is produced either by the oxidation, or the destructive distillation, of organic bodies containing its elements — carbon, hydrogen, and oxygen.

The oxidation of organic bodies, in order to convert them into acetic acid, may be effected either,— 1, by exposing them in a finely divided state to the action of air or oxygen gas; 2, by submitting them to the action of ferments in the presence of a free supply of atmospheric air; or, 3, by the action of chemical oxidising agents.

When acetic acid is procured by the *oxidation* of organic bodies, it is generally alcohol that is employed; but by whatever process alcohol is transformed into acetic acid, it is always first converted into an intermediate compound, aldehyde; and this

* Numbers, vi. 3.
‡ Livy.
‖ Westendorf, Diss. de opt. acet. conc. &c. Gottenburg, 1772.
¶ Lowitz, Allgem. Journal von Likerer, III. 600.
† De natura mulierbri.
§ Investigation of Perfection.

Digitized by Google

being a very volatile body, it is desirable always to effect the oxidation as completely and rapidly as possible, to avoid the loss of alcohol by the evaporation of this aldehyde.

Alcohol contains	$C^4 H^6 O^2$
Aldehyde „	$C^4 H^4 O^2$
Acetic acid „	$C^4 H^4 O^4$

The process, therefore, consists first in the removal of two equivalents of hydrogen from alcohol, which are converted into water,—aldehyde being produced,—and then the further union of this aldehyde with two equivalents of oxygen to convert it into acetic acid. See ALDEHYDE.

By the oxidation of alcohol, pure acetic acid is obtained: but the vinegars of commerce are mixtures of the pure acetic acid with water; with saccharine, gummy, and colouring matters; with certain ethers (especially the acetic ether), upon which their agreeable aromatic flavour depends; with empyreumatic oils, &c.

The pure acetic acid (free from water and other impurities) may be obtained most advantageously, according to Melsens*, by distilling pure acetate of potash with an excess of acetic acid (which has been obtained by the redistillation of ordinary acetic acid, procured either by oxidising alcohol, or by the destructive distillation of wood): the acid which first passes over contains water; but finally it is obtained free.

Properties of pure Acetic Acid. — When absolutely pure, acetic acid is a colourless liquid of specific gravity 1·064, which at temperatures below 62° F. (17° C.) solidifies into a colourless crystalline mass. It has strongly acid properties, being as powerfully corrosive as many mineral acids, causing vesication when applied to the skin; and it possesses a peculiarly pungent, though not a disagreeable smell.

The vapour of the boiling acid is highly combustible, and burns with a blue flame. Hydrated acetic acid dissolves camphor, gliadine, resins, the fibrine of blood, and several organic compounds. When its vapour is conducted through a slightly ignited porcelain tube, it is converted entirely into carbonic acid and acetone, an atom of the acid being resolved into an atom of each of the resultants. At a white heat the acid vapour is converted into carbonic acid, carburetted hydrogen, and water.

It attracts water with great avidity, mixing with it in all proportions. Its solution in water increases in density with the increase of acetic acid up to a certain point; but beyond this point its density again diminishes. Its maximum density being 1·073, and corresponding to an acid containing $C^4 H^4 O^4 + 2Aq.$, which may be extemporaneously produced by mixing 77·2 parts of crystallised acetic acid with 22·8 parts of water. This hydrate boils at 104° C. (219° F.), whilst the crystallised acid boils only at 120° C. (248° F.)†

The proportion of acetic acid in aqueous mixtures may therefore be ascertained, within certain limits, by determination of the specific gravity. See ACETIMETRY.

The following Table, by Mohr, indicates the per-centage of acetic acid in mixtures of different specific gravities; but of course this is only applicable in cases where no sugar or other bodies are present which increase the specific gravity.

Abstract of Mohr's Table of the Specific Gravity of Mixtures of Acetic Acid and Water.‡

Acetic acid was formerly (and is still by some chemists) viewed as the hydrated teroxide of a radical, Acetyl.

$$\underbrace{(C^4 H^3)}_{\text{Acetyl.}} O^3, HO$$

And therefore an anhydrous acetic acid, $C^4 H^3 O^3$, was supposed to exist. Many attempts have been made to isolate this anhydrous acetic acid $C^4 H^3 O^3$; and a body which has received this name has been quite recently obtained by Gerhardt*, by the double decomposition of chloride of acetyl and an alkaline acetate, thus—

$$\underbrace{C^4 H^3 (O^2 Cl)}_{\text{Chloride of acetyl.}} + \underbrace{KO, C^4 H^3 O^3}_{\text{Acetate of potash.}} = \underbrace{C^8 H^6 O^6}_{\text{(So-called) Anhydrous acetic acid.}} + \underbrace{K Cl}_{\text{Chloride of potassium.}}$$

This body Gerhardt describes as a colourless liquid having a strong smell of acetic acid, but associated with the flavour of hawthorn blossom, having a specific gravity of 1·073, and boiling at 137° C. (278° F.); falling in water in the form of oily drops, only dissolving on gently heating that fluid. It is, however, not anhydrous acetic acid, but a compound isomeric with the hypothetical anhydrous acetic acid $C^4 H^3 O^3$, containing, in fact, double the amount of matter, its formula being $C^8 H^6 O^6$. See ISOMERISM.

The impure varieties of acetic acid known as vinegar, pyroligneous acid, &c., are the products met with in commerce, and therefore those require more minute description in this work.

Before describing the manufacture of these commercial articles, it may be interesting to allude to a method of oxidising alcohol by means of spongy platinum; which may yet meet with extensive practical application. It is a well-known fact that spongy platinum (*e.g.* platinum black), from its minute state of division, condenses the oxygen of the air within its pores; consequently, when the vapour of alcohol comes in contact with this body, a supply of oxygen in a concentrated state is presented to it, and the platinum, without losing any of its properties, effects the combination between the oxygen and the alcohol, converting the latter into acetic acid.

This may be illustrated by a very simple experiment. Place recently ignited spongy platinum, loosely distributed on a platinum-gauze, at a short distance over a saucer containing warm alcohol, the whole standing under a bell-glass supported by wedges on a glass dish, so that on removing the stopper from the bell-glass a slow current of air circulates through the apparatus; the spongy platinum soon begins to glow, in consequence of the combustion going on upon its surface, and acetic acid vapours are abundantly produced, which condense and run down the sides of the glass. The simultaneous formation of aldehyde is, at the same time, abundantly proved by its peculiar odour.

In Germany this method has been actually carried out on the large scale, and, if it were not for the high price of platinum and the heavy duty on alcohol, it might be

* Comptes rendus. xxxiv. 755.

extensively employed in this country, on account of its elegance and extreme simplicity. See ACETAL.

MANUFACTURE OF VINEGAR

A.—*By acetous Fermentation.*

All liquids which are susceptible of the vinous fermentation are capable of yielding vinegar. A solution of sugar is the essential ingredient, which is converted first into alcohol, and subsequently into acetic acid. The liquids employed vary according to circumstances. In this country the vinegar of commerce is obtained from an infusion of malt, and in wine countries from inferior wines.

The oxidation of alcohol is remarkably facilitated by the presence of nitrogenised organic bodies in a state of change, called *ferments*, hence the process is frequently termed *acetous fermentation*. Now, although in most cases the presence of these ferments curiously promotes the process, yet they have no specific action of this kind; for we have already seen that, by exposure to air in a condensed state, alcohol, even when pure, is converted into acetic acid; and, moreover, the action of oxidising agents, such as chromic and nitric acid, &c., is capable of effecting this change.

However, in the presence of a ferment, with a free supply of air, and at a temperature of from 60° to 90° F., alcohol is abundantly converted into acetic acid.

At the same time that the alcohol is converted into acetic acid, the nitrogenised and other organic matters undergo peculiar changes, and often a white gelatinous mass is deposited,—which contains Vibriones and other of the lower forms of organised beings,—and which has received the name of *mother of vinegar**, from the supposition that the formation and development of this body, instead of being a secondary result of the process, was really its exciting cause.

1. WINE VINEGAR. (*Vinaigre*, Fr.; *Weinessig*, Germ.) Wine vinegar is made of the best quality, and on the greatest scale, at Orleans in France, out of wines which have become more or less acidulous, and are, therefore, of inferior value. When the vinegar is made from well-flavoured wines, it is preferable to every other for the use of the table. The old method pursued in the *vinaigreries* consists merely in partially filling a series of large casks placed in three or four ranges over each other, in a cellar warmed with a stove to the temperature of 85° F., with the wine mixed with a certain proportion of ready-made vinegar as a ferment. Low-roofed apartments are the most suitable; when there is a high ceiling it is necessary to elevate the "mothers," in order that they may occupy the higher strata of warm air. This trouble is dispensed with when the roofs are low. Experience has proved that in high-roofed apartments, where the tuns are placed at different levels, the uppermost work off quicker and better than the others. More wine is added, in successive small portions, as fast as the first has become acetified, taking care that a free ventilation be maintained, in order to replace the carbonic acid produced by fresh atmospheric oxygen. In summer, under a favourable exposure of the windows and walls of the fermenting room to the sun, artificial heat is not needed. Each cask is of about 60 gallons' capacity, and into each cask of the set is poured $\frac{1}{3}$rd its capacity of vinegar, to which 2 galls. of wine are added, and weekly, afterwards, 2 galls. more. About 8 galls. are drawn off at the end of four weeks as vinegar, and then successive additions of wine are made as before to the casks. These are laid horizontally in rows upon their gawntrees, and are pierced at the upper surface of the front end with two holes: one, called the *eye*, is two inches in diameter, and serves for pouring in the charges through a funnel; the other is a small air-hole alongside. The casks should never be more than $\frac{3}{4}$rds full, otherwise a sufficient body of air is not present in them for favouring rapid acetification. At the end of a certain period, the deposit of tartar and lees becomes so great that the casks must be cleared out. This renovation usually takes place every 10 years; but the casks, when made of well-seasoned oak and bound with iron hoops, will last 25 years. The wine, as well the vinegar produced, should be clarified by being slowly filtered through beech chips, closely packed in a large open tun. When wines are new, and somewhat saccharine or too alcoholic, they acetify reluctantly, and need the addition of a little yeast, or even water, to the mixture; and when they are too weak, they should be enriched by the addition of some sugar or stronger wine, so as to bring them to a uniform state for producing vinegar of normal strength. To favour the renewal of fresh air into the upper part of the hogsheads, it would be advisable to pierce a two-inch hole near to the upper level of the liquid when the cask is fullest, by which means the heavy carbonic acid would fall out, and be replaced by the atmospheric air at the superior apertures.

* This substance has been supposed by some to be a fungus, and has been described by Mulder under the name of Mycoderma Aceti, or Vini.

Digitized by Google

Wine vinegar is of two kinds, *white* and *red*, according as it is prepared from white or red wine. *White wine vinegar* is usually preferred, and that made at Orleans is regarded as the best.

Dr. Ure found its average specific gravity to be 1·019, and to contain from 6½ to 7 per cent. of real acid; according to the Edinburgh Pharmacopœia, its specific gravity varies from 1·014 to 1·022.

2 MALT VINEGAR. (*British Vinegar*; in Germany called *Malz-Getreide* or *Bier-essig*.) In England vinegar is chiefly made from an infusion of malt, by first exciting in it the alcoholic fermentation, and subsequently inducing the oxidation of the alcohol into acetic acid.

For details of the processes of *malting* and *brewing* the alcoholic liquor, we must refer to the special articles on these subjects, confining our attention here more especially to the latter stages of the operation.

From 6 bushels of malt, properly crushed, 100 gallons of wort may be extracted by due mashing, the first water of infusion being of the temperature of 160° F., and the next two progressively hotter, for exhausting the soluble saccharine matter. When the wort is cooled to 75°, from 3 to 4 gallons of good yeast are stirred into it in the fermenting tun, and when it has been in brisk fermentation for about 40 hours, it is ready for transference into the vessels in which the acetification is to be accomplished.

The transformation of the fermented wort into vinegar was formerly effected in two ways, which were entirely opposite in their manner of operation. In one case the casks containing the fermented malt infusion (or *gyle*) were placed in close rooms, maintained at a uniform temperature, as already described in the preparation of wine vinegar; in the other, they were arranged in rows in an open field, where they remained many months. As regards the convenience and interests of the manufacturer, it appears that each method had its respective advantages, but both are now almost entirely abandoned for the more modern processes to be described — a short notice of the fielding process is, however, retained.

When *fielding* is resorted to, it must be commenced in the spring months, and then left to complete itself during the warm season. The *fielding* method requires a much larger extent of space and utensils than the stoving process. The casks are placed in several parallel tiers, with their bung side upwards and left open. Beneath some of the paths which separate the rows of cask are pipes communicating with the "*back*" at the top of the brewhouse; and in the centre of each is a valve, opening into a concealed pipe. When the casks are about to be filled, a flexible hose is screwed on to this opening, the other end being inserted into the bung-hole of the cask, and the liquor in the "*gyle back*" at the brewhouse, by its hydrostatic pressure, flows through the underlying pipe and hose into the cask. The hose is so long as to admit of reaching all the casks in the same row, and is guided by a workman.

After some months the vinegar is made, and is drawn off by the following operation: a long trough or sluice is laid by the side of one of the rows of casks, into which the vinegar is transferred by means of a syphon, whose shorter limb is inserted into the bung-hole of the cask. The trough inclines a little from one end to the other, and its lower end rests on a kind of travelling tank or cistern, wherein the vinegar from several casks is collected. A hose descends from the tank to the open valve of an underground pipe, which terminates in one of the buildings or stores, and, by the agency of a steam boiler and machinery, the pipe is exhausted of its air, and this causes the vinegar to flow through the hose into the valve of the pipe, and thence into the factory buildings. By this arrangement the whole of the vinegar is speedily drawn off. From the storehouse, where the vinegar is received, it is pumped into the *refining* or *rape* vessels.

These rape vessels are generally filled with the stalks and skins of grapes or raisins (the refuse of the British wine manufacture is generally used), and the liquor being admitted at the top, is allowed slowly to filter through them; after passing through, it is pumped up again to the top, and this process is repeated until the acetification is complete. Sometimes wood shavings, straw, or spent tan, are substituted for the grape refuse, but the latter is generally preferred.

By this process, not only is the oxidation of the alcohol completed, but coagulable nitrogenous and mucilaginous matter is separated, and thus the vinegar rendered *bright*. It is finally pumped into store vats, where it is kept until put into casks for sale.

3. SUGAR, CIDER, FRUIT, AND BEET VINEGARS. An excellent vinegar may be made for domestic purposes by adding, to a syrup consisting of one pound and a quarter of sugar for every gallon of water, a quarter of a pint of good yeast. The liquor being maintained at a heat of from 75° to 80° F., acetification will proceed so well that

Digitized by Google

in 2 or 3 days it may be racked off from the sediment into the ripening cask, where it is to be mixed with 1 oz. of cream of tartar and 1 oz. of crushed raisins. When completely freed from the sweet taste, it should be drawn off clear into bottles, and closely corked up. The juices of currants, gooseberries, and many other indigenous fruits, may be acetified either alone or in combination with syrup. Vinegar made by the above process from sugar should have fully the Revenue strength. It will keep much better than malt vinegar, on account of the absence of gluten, and at the present low price of sugar will not cost more, when fined upon beech chips, than 1s. per gallon.

The sugar solution may likewise be replaced by honey, cider, or any other alcoholic or saccharine liquid. An endless number of prescriptions exist, of which the following example may suffice:—100 parts of water to 13 of brandy, 4 of honey, and 1 of tartar.

Messrs. Neale and Duyck, of London, patented a process, in 1841, for the manufacture of vinegar from *beet-root*.

The saccharine juice is pressed out of the beet, previously rasped to a pulp, then mixed with water and boiled; this solution is fermented with yeast, and finally acetified in the usual way, the process being accelerated by blowing air up through the liquid, which is placed in a cylindrical vessel with fine holes at the bottom.

In some factories large quantities of sour ale and beer are converted into vinegar; but it is usually of an inferior quality, in consequence of being liable to further fermentation.

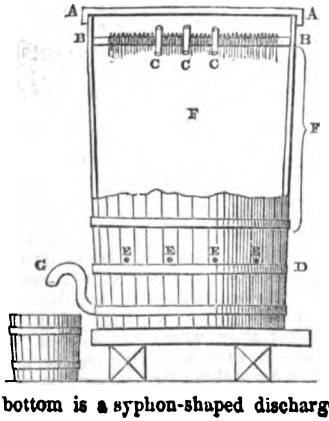
Dr. Stenhouse has shown that when *sea-weed* is subjected to fermentation, at a temperature of 96° F., in the presence of lime, acetate of lime is formed, from which acetic acid may be liberated by the processes described under the head of Pyroligneous Acid. Although such large quantities of sea-weed are found on all our coasts, it does not yet appear that they have yet been utilised in this way, although they would still be, to a certain extent, valuable as manure after having been subjected to this process.

4. The German or Quick-Vinegar Process. (*Schnellessigbereitung.*)—In the manufacture of vinegar it is highly important that as free a supply of air should be admitted to the liquid as possible, since if the oxidation take place but slowly, a considerable loss may be sustained from much of the alcohol, instead of being completely oxidised to acetic acid, being only converted into aldehyde, which, on account of its volatility, passes off in the state of vapour. This is secured in the German process by greatly enlarging the surface exposed to the air; which, however, not only diminishes or prevents the formation of aldehyde, but also greatly curtails the time necessary for the whole process. In fact, when this method was first introduced, from the supply of air being insufficient, very great loss was sustained from this cause, which was, however, easily remedied by increasing the number of air-holes in the apparatus.

This *quick-vinegar process* consists in passing the fermented liquor (which generally contains about 50 gallons of brandy of 60 per cent., and 37 gallons of beer or malt-wort, with $\frac{1}{1000}$ of ferment,) two or three times through an apparatus called the Vinegar Generator (*essigbilder*).

This apparatus consists of an oaken tub, narrower at the bottom than at the top, furnished with a loose lid, A, with a funnel, through which the liquids for charging the graduator are supplied; below this is a perforated shelf, B, having a number of small holes, loosely filled with packthread, about six inches long, and prevented from falling through by a knot at the upper end. Through this lid there likewise pass some glass tubes, open at both ends, C, which, having their apertures above and below the shelf, act as air vents. At a distance of about eighteen inches from the bottom is placed another perforated diaphragm, at D; and two inches above this the tub is perforated with eight or ten equidistant holes, E E, an inch to an inch and a half in diameter, which serve to admit atmospheric air. The space, F, between the diaphragm and the perforated lid, is filled with shavings of beechwood; by percolating through which, the solution is exposed, over a very considerable surface, to the oxidising influence of the air, which passes in a current upwards through the apparatus. One inch above the bottom is a syphon-shaped discharge

1



Digitized by Google

pipe, a, the upper curvature of which stands one inch below the air-holes in the side of the tub; so that when the liquid in the bottom of the generator, which has passed through the shavings, collects up to this level, it runs off into any vessel placed beneath to receive it.

The analogy between acetification and ordinary processes of decay, and even combustion, is well seen in this process; for as the oxidation proceeds, the temperature of the liquid rises to 100° or even 104° F.; but if the temperature generated by the process itself be not sufficient, the temperature of the room in which the tuns are placed should be artificially raised.

By this method 150 gallons of vinegar can be manufactured daily in ten tuns, which one man can superintend; and the vinegar, in purity and clearness, resembles distilled vinegar.

It is better to avoid using liquors containing much suspended mucilaginous matter, which, collecting on the chips, quickly chokes up the apparatus, and not only impedes the process, but contaminates the product.

The chips and shavings may with advantage be replaced by charcoal in fragments, which, by the oxygen it contains condensed in its pores, still further accelerates the process. The charcoal would of course require re-igniting from time to time.

Processes for the rapid formation of vinegar have likewise been adopted in this country. So long ago as the year 1824, Mr. Ham obtained a patent for the following method, which is still in operation at several works:—

The apparatus consists of a large vat, in the centre of which is placed a revolving pump, having two or more shoots pierced with holes, so as to cause a constant shower of wash—fermented wort—to descend. The lower part of the vat is charged with wash, the upper part with birch twigs, piled as high as possible, but without interfering with the revolution of the shoots. Between the surface of the wash and the joist which supports the birch twigs, a space of three or four inches is unoccupied, and holes are perforated in it, to admit a current of air, either from the atmosphere or from a blowing apparatus.

If the wash be maintained at a temperature of from 90 to 100° F., and the supply of liquid duly proportioned to the mass of the twigs, a charge is generally acetified in about a fortnight. The acetification can of course be arrested at any moment, and the current of air increased or diminished at will.

Generally in England much larger tuns are used than in Germany, the larger mass of matter thus undergoing oxidation generating so much heat that no artificial elevation of temperature is required; and in consequence of the promotion of the process in this way, one of these large tuns, fifteen feet wide at the bottom, fourteen at the top, and thirteen high, turns out as much vinegar as is in Germany obtained from six tubs eighteen feet high and four feet wide.

B.—*By destructive Distillation of Wood. Pyroligneous Acid.*

The general nature of the process of destructive distillation will be found detailed under the head of DISTILLLATION, DESTRUCTIVE; as well as a list of products of the rearrangement of the molecules of organic bodies under the influence of heat in closed vessels. We shall, therefore, at once proceed to the details of the process as specially applied in the manufacture of acetic acid from wood.

The forms of apparatus very generally employed on the Continent for obtaining at the same time crude acetic acid, charcoal, and tar, are those of Schwartz and Reichenbach; but in France the process is carried out with special reference to the production of acetic acid alone.

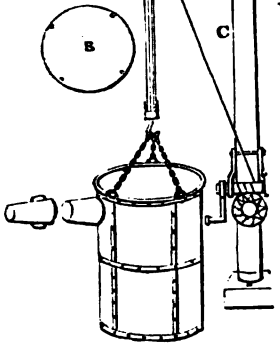
The following is a description of that in use at Nuits and Rouen:—

Into large cylindrical vessels (*fig.* 2) made of rivetted sheet iron, and having at their top and side a small sheet-iron cylinder, the wood intended for making charcoal is introduced. To the upper part of this vessel a cover of sheet iron, B, is adapted, which is fixed with bolts. This vessel, thus closed, represents, as we see, a vast retort. When it is prepared, as we have said, it is lifted by means of a swing crane, C, and placed in a furnace, D (*fig.* 3), of a form relative to that of the vessel, and the opening of the furnace is covered with a dome, E, made of masonry or brickwork. The whole being thus arranged, heat is applied in the furnace at the bottom. The moisture of the wood is first dissipated, but by degrees the liquor ceases to be transparent, and becomes sooty. An adapter tube, A, is then fitted to the lateral cylinder. This adapter enters into another tube at the same degree of inclination which commences the condensing apparatus. The means of condensation vary according to the localities. In certain works they cool by means of air, by making the vapour pass through a long series of cylinders, or sometimes, even, through a series of casks connected together; but most usually water is used for condensing, when it can be easily procured in abundance. The most

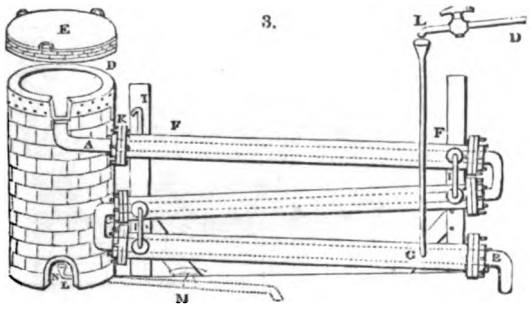
Digitized by Google

simple apparatus employed for this purpose consists of two cylinders, F F (*fig.* 3), the one within the other, and which leave between them a sufficient space to allow a considerable body of water to circulate along and cool the vapours. This double cylinder is adapted to the distilling vessel, and placed at a certain inclination. To the first double tube, F F, a second, and sometimes a third, entirely similar, are connected, which, to save space, return upon themselves in a zigzag fashion. The water is set in circulation by an ingenious means now adopted in many different manufactories. From the lower extremity, G, of the system of condensers, a perpendicular tube rises, whose length should be a little more than the most elevated point of the system. The water, furnished by a

2



3.



reservoir, L, enters by means of the perpendicular tube through the lower part of the system, and fills the whole space between the double cylinders. When the apparatus is in action, the vapours, as they condense, raise the temperature of the water, which, by the column in L G, is pressed to the upper part of the cylinders, and runs over by the spout R. To this point a very short tube is attached, which is bent towards the ground, and serves as an overflow.

The condensing apparatus is terminated by a conduit in bricks covered and sunk in the ground. At the extremity of this species of gutter is a bent tube, E, which, discharges the liquid product into the first cistern. When it is full, it empties itself, by means of an overflow pipe, into a great reservoir; the tube which terminates the gutter plunges into the liquid, and thus intercepts communication with the inside of the apparatus. The disengaged gas is brought back, by means of pipes M L, from one of the sides of the conduit to the under part of the ashpit of the furnace. These pipes are furnished with stopcocks, M, at some distance in front of the furnace, for the purpose of regulating the jet of the gas, and interrupting, at pleasure, communication with the inside of the apparatus. The part of the pipes which terminates in the furnace rises perpendicularly several inches above the ground, and is expanded like the rose of a watering-can, N. The gas, by means of this disposition, can distribute itself uniformly under the vessel, without suffering the pipe which conducts it to be obstructed by the fuel or the ashes.

The temperature necessary to effect the carbonisation is not at first considerable: however, at the last, it is raised so high as to make the vessels red hot; and the duration of the process is necessarily proportional to the quantity of wood carbonised. For a vessel which shall contain about 5 meters cube (nearly 6 cubic yards), 8 hours of fire is sufficient. It is known that the carbonisation is complete by the colour of the flame of the gas: it is first of a yellowish red; it becomes afterwards blue, when more carbonic oxide than carburetted hydrogen is evolved; and towards the end it becomes entirely white, — a circumstance owing, probably, to the furnace being more heated at this period, and the combustion therefore more complete. There is still another means of knowing the state of the process, to which recourse is more frequently had; that is the cooling of the first tubes, which are not surrounded with water: a few drops of this fluid are thrown upon their surface, and if they evaporate quietly, it is judged that the calcination is sufficient. The adapter tube is then unluted, and is slid into its junction pipe; the orifices are immediately stopped with plates of iron and plaster loam. The brick cover, E, of the furnace is first removed by means of the swing crane. then the cylinder itself is lifted out and replaced immediately by another one previously charged. When the cylinder which has been

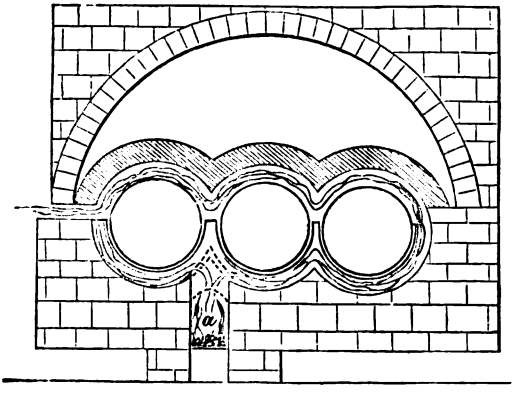
Digitized by Google

taken out of the furnace is entirely cooled, its cover is removed, and the charcoal is emptied. Five cubic meters of wood furnish about 7 chaldrons and a half of charcoal.

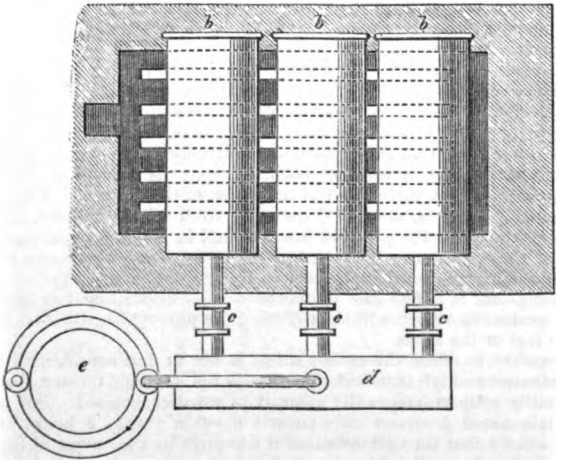
The carbonisers of Reichenbach and Schwartz are usually employed with special reference to the manufacture of wood-charcoal, the condensation of the volatile products being only a secondary consideration.

In England the distillation of wood, with especial reference to the manufacture of pyroligneous acid, is generally carried out in large iron retorts, placed horizontally in the furnace; the process, in fact, closely resembling the distillation of coal in the manufacture of coal gas, excepting that the retorts are generally larger, being sometimes 4 feet in diameter, and 6 or 8 feet long. Generally two, or even three, are placed in each furnace, as shown in *fig.* 4, so that the fire of the single furnace, *a*, plays all round them. The doors for charging the retorts are at one end, *b* (*fig.* 5), and the pipe for carrying off the volatile products at the other, *c*, by which they are conducted, first to the tar condenser, *d*, and finally through a worm in a large tub, *e*, where the crude acetic acid is collected.

4



5



Of course, in different localities an endless variety of modifications of the process are employed.

In the Forest of Dean, instead of cylindrical retorts, square sheet-iron boxes are used, 4 ft. 6 in. by 2 ft. 9 in., which are heated in large square ovens.

Dr. Ure gives the following description of special works in Glasgow:—

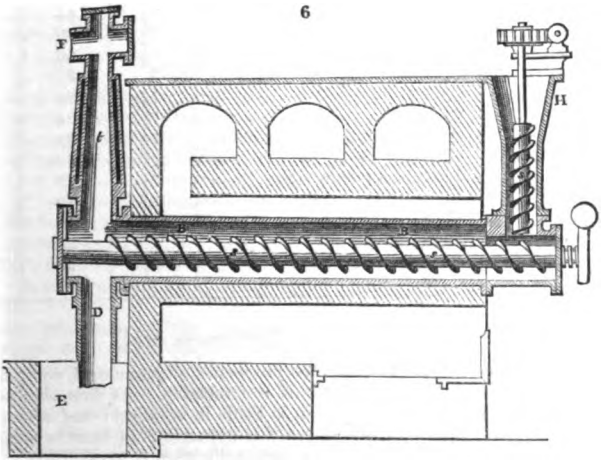
The cylinders here employed are 6 feet long, and both ends project a little beyond the brickwork. One end has a disc, or round plate of cast-iron, well fitted and firmly bolted to it, from the centre of which an iron tube, about 6 inches in diameter, proceeds, and enters at a right angle the main tube of refrigeration. The diameter of this tube may be from 9 to 14 inches, according to the number of cylinders. The other end of the cylinder is called the mouth of the retort; this is closed by a disc of iron, smeared round its edge with clay-lute, and secured in its place by iron wedges. The charge of wood for such a cylinder is about 8 cwt. The hard woods — oak, ash, birch, and beech — are alone used in this manufactory, fir not being found to answer. The heat is kept up during the day, and the furnace allowed to cool during

Digitized by Google

the night. Next morning the door is opened, the charcoal removed, and a new charge of wood introduced. The average product of crude vinegar is 35 gallons. It is much contaminated with tar, is of a deep brown colour, and has a specific gravity of 1·025. Its total weight is therefore about 300 lbs.; but the residuary charcoal is found to weigh no more than one-fifth of the wood employed; hence nearly one-half of the ponderable matter of the wood is dissipated in incondensable gases.

With regard to the relative advantages of cylindrical retorts or square boxes, it should be remarked, that the cylinders are more adapted for the distillation of the large billets of Gloucestershire and the refuse ship timber of Glasgow, Newcastle, and Liverpool; but, on the other hand, where light wood is used, such as that generally carbonised in the Welsh factories, the square ovens answer better.

6



The most recent and ingenious improvement in the manufacture of pyroligneous acid is that patented by the late Mr. A. G. Halliday, of Manchester, and adopted by several large manufacturers. The process consists in effecting the destructive distillation of waste materials, such as sawdust and spent dyewoods, by causing them to pass in continuous motion through heated retorts. For this purpose the materials, which are almost in a state of powder, are introduced into a hopper, H (*fig.* 6), whence they descend into the retort, B, being kept all the while in constant agitation, and at the same time moved forward to the other end of the retort by means of an endless screw, *s*. By the time they arrive there, the charge has been completely carbonised, and all the pyroligneous acid evolved at the exit tube, *t*. The residuary charcoal falls through the pipe D into a vessel of water, E, whilst the volatile products escape at F, and are condensed in the usual way.

Several of these retorts are generally set in a furnace side by side, the retorts are only 14 inches in diameter, and eight of these retorts produce in 24 hours as much acid as 16 retorts 3 feet in diameter upon the old system. In the manufacturing districts of Lancashire and Yorkshire, where such immense quantities of spent dyewoods accumulate, and have proved a source of annoyance and expense for their removal, this process has afforded a most important means of economically converting them into valuable products — charcoal and acetic acid.

Mention should also be made of Messrs. Solomons and Azulay's patent for employing superheated steam to effect the carbonisation of the wood, which is passed directly into the mass of materials. Since the steam accompanies the volatile products, it necessarily dilutes the acid; but this is in a great degree compensated for by employing these vapours to concentrate the distilled products, by causing them to traverse a coil of tubing placed in a pan of the distillates.

As regards the yield of acetic acid from the different kinds of wood, some valuable facts have been collected and tabulated by Stolze, in his work on Pyroligneous Acid:—

Properties of the crude Pyroligneous Acid.

The crude pyroligneous acid possesses the properties of acetic acid, combined with those of the pyrogenous bodies with which it is associated. As first obtained, it is black, from the large quantity of tar which it holds in solution; and although certain resins are removed by redistillation, yet it is impossible to remove some of the empyreumatic oils by this process, and a special purification is necessary.

In consequence of the presence of creosote, and other antiseptic hydrocarbons, in the crude pyroligneous acid, it possesses, in a very eminent degree, anti-putrescent properties. Flesh steeped in it for a few hours may be afterwards dried in the air without corrupting; but it becomes hard, and somewhat leather-like: so that this mode of preservation does not answer well for butcher's meat. Fish are sometimes cured with it.

Purification of Pyroligneous Acid.

This is effected either, 1st, by converting it into an acetate, — acetate of lime or soda, — and then, after the purification of these salts by exposure to heat sufficient to destroy the tar, and repeated recrystallisation, liberating the acid again by distilling with a stronger acid, *e.g.* sulphuric.

Or, 2nd, by destroying the pyrogenous impurities by oxidising agents, such as binoxide of manganese in the presence of sulphuric acid, &c.

The former is the method generally adopted.

After the naphtha has been expelled, the acid liquor is run off into tanks to deposit part of its impurities; it is then syphoned off into another vessel, in which is either milk of lime, quicklime, or chalk; the mixture is boiled for a short time, and then allowed to stand for 24 hours to deposit the excess of lime with any impurities which the latter will carry down with it. The supernatant liquor is then pumped into the evaporating pans.

The evaporation is effected either by the heat of a fire applied beneath the evaporating pans, or more frequently by a coil of pipe in the liquor through which steam is passed — the liquor being kept constantly stirred, and the impurities which rise to the surface during the process carefully skimmed off.

From time to time, as the evaporation advances, the acetate of lime which separates is removed by ladles, and placed in baskets to drain; and the residual mother-liquor is evaporated to dryness. This mass, by ignition, is converted into carbonate of lime and acetone.

If the acetate of lime have been procured by directly saturating the crude acid, it is called *brown acetate*; if from the acid once purified by redistillation, it is called *grey acetate*.

Digitized by Google

From this grey acetate of lime acetate of soda is now prepared, by adding sulphate of soda to the filtered solution of the acetate of lime. In performing this operation, it is highly important to remember that, for every equivalent of acetate of lime, it is necessary to add two equivalents of sulphate of soda, on account of the formation of a double sulphate of soda and lime. The equation representing the change being:—

$$\underbrace{CaO, C^4H^3O^3}_{\text{Acetate of lime.}} + 2(NaO, SO^3) = \underbrace{NaO, C^4H^3O^3}_{\text{Acetate of soda.}} + \underbrace{CaO, SO^3. \ NaO, SO^3}_{\text{Double salt.}}$$

Or, if sulphuric acid be considered as a bibasic acid, which this very re-action so strongly justifies—

$$\underbrace{C^4H^3(Ca)O^4}_{\text{Acetate of lime.}} + \underbrace{Na^2S^2O^8}_{\text{Sulphate of soda.}} = \underbrace{C^4H^3(Na)O^4}_{\text{Acetate of soda.}} + \underbrace{\left.\begin{matrix}Ca\\Na\end{matrix}\right\rangle S^2O^8}_{\text{Double salt.}}$$

If this point be neglected, and only one equivalent of sulphate of soda be used, one-half of the acetate of lime may escape decomposition, and thus be lost.

After the separation of the double salt, the solution of acetate of soda is drawn off, any impurities allowed to subside, and then concentrated by evaporation until it has a density of 4·3 — when the acetate of soda crystallises out, and may be further purified, if requisite, by another re-solution and re-crystallisation. The contents of the mother liquors are converted into acetone and carbonate of soda, as before.

The crystallised acetate of soda is now fused in an iron pot, at a temperature of about 400°, to drive off the water of crystallisation, the mass being kept constantly stirred. A stronger heat must not be applied, or we should effect the decomposition of the salt.

For the production of the acetic acid from this salt, a quantity of it is put into a stout copper still, and a deep cavity made in the centre of the mass, into which sulphuric acid of specific gravity 1·84 is poured in the proportion of 35 per cent. of the weight of the salt; the walls of the cavity are thrown in upon the acid, the whole briskly agitated with a wooden spatula. The head of the still is then luted, and connected with the condensing worm, and the distillation carried on at a very gentle heat. The worm should be of silver or porcelain, as also the still head; and even silver solder should be used to connect the joinings in the body of the still. The still is now generally heated by a steam "jacket." See DISTILLATION.

The acid which passes over is nearly colourless, and has a specific gravity of 1·05. That which collects at the latter part of the operation is liable to be somewhat empyreumatic, and therefore before this point is reached the receiver should be changed; and throughout the entire operation, care should be taken to avoid applying too high a temperature, as the flavour and purity of the acid will invariably suffer.

Any trace of empyreuma may be removed from the acid by digestion with animal charcoal and redistillation.

A considerable portion of this acid crystallises at a temperature of from 40° to 50° F., constituting what is called *glacial acetic acid*, which is the compound $C^4H^4O^4$ (or $C^4H^3O^3$, HO).

For culinary purposes, pickling, &c., the acid of specific gravity 1·05 is diluted with five times its weight of water, which renders it of the same strength as Revenue proof vinegar.

Several modifications and improvements of this process have recently been introduced, which require to be noticed.

The following process depends upon the difficult solubility of sulphate of soda in strong acetic acids:—100 lbs. of the pulverised salt being put into a hard glazed stoneware receiver, or deep pan, from 35 to 36 lbs. of concentrated sulphuric acid are poured in one stream upon the powder, so as to flow under it. The mixture of the salt and acid is to be made very slowly, in order to moderate the action and the heat generated, as much as possible. After the materials have been in intimate contact for a few hours, the decomposition is effected; sulphate of soda in crystalline grains will occupy the bottom of the vessel, and acetic acid the upper portion, partly liquid and partly in crystals. A small portion of pure acetate of lime added to the acid will free it from any remainder of sulphate of soda, leaving only a little acetate in its place; and though a small portion of sulphate of soda may still remain, it is unimportant, whereas the presence of any free sulphuric acid would be very injurious. This is easily detected by evaporating a little of the liquid, at a moderate heat, to dryness, when that mineral acid can be distinguished from the neutral soda sulphate. This plan of superseding a troublesome distillation, which is due to M. Mollerat, is one of the greatest improvements in this process, and depends upon the insolubility of the

Digitized by Google

sulphate of soda in acetic acid. The sulphate of soda thus recovered, and well drained, serves anew to decompose acetate of lime; so that nothing but this cheap earth is consumed in carrying on the manufacture. To obtain absolutely pure acetic acid, the above acid has to be distilled in a glass retort.

Völckel recommends the use of hydrochloric instead of sulphuric acid for decomposing the acetate.

The following is his description of the details of the process:—

"The crude acetate of lime is separated from the tarry bodies which are deposited on neutralisation, and evaporated to about one-half its bulk in an iron pan. Hydrochloric acid is then added until a distinctly acid reaction is produced on cooling; by this means the resinous bodies are separated, and come to the surface of the boiling liquid in a melted state, whence they can be removed by skimming, while the compounds of lime, with creosote, and other volatile bodies, are likewise decomposed, and expelled on further evaporation. From 4 to 6 lbs. of hydrochloric acid for every 33 gallons of wood vinegar is the average quantity required for this purpose. The acetate having been dried at a high temperature on iron plates, to char and drive off the remainder of the tar and resinous bodies, is then decomposed, by hydrochloric acid, in a still with a copper head and leaden condensing tube. To every 100 lbs. of salt about 90 to 95 lbs. of hydrochloric acid of specific gravity 1·16 are required. The acid comes over at a temperature of from 100° to 120° C. (212° to 248° F.), and is very slightly impregnated with empyreumatic products, while a mere cloud is produced in it by nitrate of silver. The specific gravity of the product varies from 1·058 to 1·061, and contains more than 40 per cent. of real acid; but as it is seldom required of this strength, it is well to dilute the 90 parts of hydrochloric acid with 25 parts of water. These proportions then yield from 95 to 100 parts of acetic acid of specific gravity 1·015.

This process is recommended on the score of economy and greater purity of product. The volatile empyreumatic bodies are said to be more easily separated by the use of hydrochloric than sulphuric acid; moreover, the chloride of calcium being a more easily fusible salt than the sulphate of lime, or even than the double sulphate of lime and soda, the acetic acid is more freely evolved from the mixture. The resinous bodies also decompose sulphuric acid towards the end of the operation, giving rise to sulphurous acid, sulphuretted hydrogen, &c., which contaminate the product.

The decomposition of acetate of lime or lead by means of sulphuric acid has many inconveniences, and there is danger of the product being contaminated with sulphuric acid. Christl* was therefore induced to employ hydrochloric acid as a decomposing agent, and has found that when this acid is not used in excess, the distillate contains scarcely an appreciable trace of chlorine. A mixture of 100 lbs. of raw acetate of lime, obtained from the distillation of wood, and containing 90 per cent. of neutral acetate, with 120 lbs. of hydrochloric acid (20° Baumé) is allowed to stand during a night, and then distilled in a copper vessel. The application of heat requires to be gradual, in order to prevent the somewhat thick liquor from running over. The product of acetic acid amounts to about 100 lbs. of 8° B.; it has a faint yellow colour and empyreumatic odour, which may be perfectly removed by treatment with wood charcoal and subsequent rectification.

In order to obtain the acetate of lime sufficiently pure, Völckel† adopts the following process:—The raw pyroligneous acid is saturated with lime without previous distillation. A part of the resinous substances dissolved in the acid are thus separated in combination with lime. The solution of impure acetate of lime is allowed to stand until it becomes clear, or it is filtered, then evaporated in an iron pan to about one-half, and hydrochloric acid added until a drop of the cooled liquid distinctly reddens litmus-paper. A part is sometimes distilled off in a copper still, in order to obtain wood-spirit. The addition of acid serves to separate a great part of the resin still held in solution, which collects together in the boiling liquid, and may be skimmed off, and likewise decomposes the compounds of lime with creosote, and some other imperfectly-known volatile substances which are driven off by further evaporation. As these volatile substances have little or no action upon litmus-paper, its being reddened by the liquor is a sign, that not only are the lime compounds of these substances decomposed, but also a small quantity of acetate of lime. The quantity of acid necessary for this purpose varies, and depends upon the nature of the pyroligneous acid, which is again dependent upon the quantity of the water in the wood from which it is obtained. Three hundred pints of wood-liquor will require from 4 to 6 lbs. of hydrochloric acid.

The solution of acetate of lime is evaporated to dryness, and a tolerably strong heat applied at last, in order to remove all volatile substances. Both operations may be

* Dingler's Polytech. Journ. † Ann. der Chem. und Pharm.

Digitized by Google

performed in the same iron pans; but when the quantity of salt is large, the latter may be more advantageously effected upon cast-iron plates. The drying of the salt requires very great care, for the empyreumatic substances adhere very strongly to the acetate of lime, as well as to the compound of resin and acetic acid mixed with it, and when not perfectly separated, pass over with the acetic acid in the subsequent distillation with an acid, communicating to it a disagreeable odour. The drying must therefore be continued until, upon cooling, the acetate does not smell at all, or but very slightly. It then has a dirty brown colour. The acetic acid is obtained by distillation with hydrochloric acid, in a still with a copper head and leaden condenser; and when proper precautions are taken, the acetic acid does nor contain a trace of either metal. The quantity of hydrochloric acid required cannot be exactly stated, because the acetate of lime is mixed with resin, and already formed chloride of calcium. In most instances 90 or 95 parts by weight of acid, 1·16 specific gravity, are sufficient to decompose completely 100 parts of the salt, without introducing much hydrochloric acid into the distillate.

The distilled acetic acid possesses only a very faint empyreumatic odour, very different from that of the raw pyroligneous acid; it is perfectly colourless, and should only become slightly turbid on the addition of nitrate of silver. If the acid has a yellowish colour, this is owing to resin having been spirted over in the distillation. It is therefore advisable to remove the resin,—which is separated on the addition of hydrochloric acid, and floats upon the surface of the liquid,—either by skimming or filtration through a linen cloth. The distilled acid has a specific gravity ranging between 1·058 and 1·061, containing upwards of 40 per cent. of anhydrous acetic acid. It is rarely that acid of this strength is required; and as the distillation is easier when the mixture is less concentrated, water may be added before or towards the end of the distillation. Völckel recommends as convenient proportions—

100 parts of acetate of lime,
90 to 95 hydrochloric acid,
25 parts water,

which yield from 95 to 100 parts of acetic acid of 1·105 specific gravity; 150 litres of raw pyroligneous acid yield about 50 lbs. of acetic acid of the above specific gravity.

The acid prepared in this way may be still further purified by adding a small quantity of carbonate of soda and redistilling; it is thus rendered quite free from chlorine, and any remaining trace of colour is likewise removed. The slight empyreumatic smell may be removed by distilling the acid with about 2 or 3 per cent. of acid chromate of potash. Oxide of manganese is less efficacious as a purifying agent.

Although pure acetic acid may be procured by the distillation of vinegar, the whole of the acid cannot be obtained except by distilling to dryness, by which means the extractive substances are burnt, and the distillate rendered impure. In order to obviate this difficulty, Stein* proposes to add 30 lbs. of salt to every 100 lbs. of vinegar; the boiling-point is thus raised, and the acid passes over completely.

By the Quick Process of Ham, when the fermentation is finished, the greatest care ought to be taken that all access of air is excluded from the wash, and that its temperature be reduced to, and maintained at, a heat below the point where acetification commences. Those who, like Messrs. Hill, Evans, and Co., of Worcester, attach great importance to the fabrication of the best keeping vinegars, are in the habit of filtering the fermented wash, and also of storing it away for many months in a cool situation ere it is passed through the acetifier; and there cannot be a moment's doubt concerning the great value of this practice, not only as regards the appearance and flavour of the resulting vinegar, but also in respect to its dietetic and sanitary properties.

All recently fermented wash contains a quantity of partially decomposed gluten, some of which is mechanically suspended merely, but by far the larger portion exists in a state of solution through the agency of carbonic acid gas.

A filter will remove the former, but time alone can dissipate the carbonic acid and lead to the deposition of the soluble gluten. At all events, time is the only available remedy, for though heat would expel the carbonic acid, yet it would at the same time drive off the alcohol; and agitation in contact with air, though it removed the carbonic acid, would tend to the formation of acetic acid, by which the gluten would be kept in solution more decidedly than before, and thus lead to the production of a turbid, ropy, and impure vinegar, extremely liable to decompose and undergo the putrefactive fermentation. It is obvious, therefore, that the theoretical conditions needed in the treatment of fermented wort by the vinegar-maker are precisely those which we have shown to be in use at Worcester. That is to say, the gluten, when insoluble, should

* Polytech. Centralblat, 1852, p. 305.

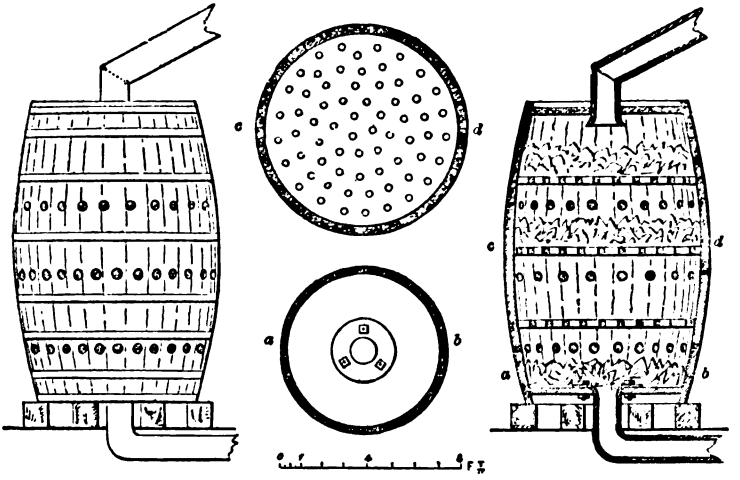
Digitized by Google

be removed by a filter, and when held in solution by carbonic acid, this must be slowly expelled by keeping at a temperature too low for acetification to take place, and which may be assumed at less than 55° F. Fermented wort stored away at this temperature for six months will flow to the acetifier perfectly limpid and bright; it will cause no deposition of gluten upon the birch twigs, and thus secure complete oxidation; it will rapidly take on the grateful flavour of acetic ether, and never become tainted by the formation of that noxious product aldehyde, which so frequently contaminates ill-made vinegar.

Presuming, however, that all the necessary precautions, with respect to care in washing, fermenting, and keeping the wort, have been attended to, we may now pass on to the acetifier, that is to say, Ham's acetifier.

This is a wooden vat or vessel (*fig.* 7) about 12 feet in height, and from 7 to

7



8 feet in diameter, closed at top and bottom, except at the opening for the introduction of the wash and the exit of the vinegar. The sides are perforated by a few small holes for the admission of air, and within are three floors or partitions perforated with numerous holes for the passage of the wash through them. Upon these floors are laid bundles of birch twigs, to favour the dispersion and division of the fluid which passes through the acetifier, and is thus brought into the most immediate contact with the oxygen contained in the vessel, or admitted through the openings in its sides. The fluid or wash is admitted at the top of the acetifier, and suffered to trickle slowly through the masses of birch twigs and through the partitions, thus causing a rapid absorption of oxygen, and consequent production of vinegar, which with any undecomposed wash flows out at the bottom of the vessel, and is again pumped up to the top, and so on until the process is finished. If we examine the circumstances connected with the formation of vinegar in this way, we shall perceive, that it is a case of partial combustion, or, in other words, an example in which an organic compound undergoes oxidation at a temperature and under conditions which prevent the completion of the change.

Every one must have observed that when common coals are thrown upon a fire, a volatile portion immediately bursts into flame, while copious particles of soot or carbon are thrown off unburnt; though of the other constituent of the coal, that is to say, the hydrogen gas, no particle escapes unoxidised. This arises from the fact, that, except at very high temperatures, hydrogen has a greater affinity for oxygen than carbon has; consequently, as the supply of oxygen from atmospheric air in the immediate neighbourhood is limited, the hydrogen seizes upon its equivalent to the exclusion of the carbon, which, therefore, remains and constitutes soot. Exactly in the same way the hydrogen of the alcohol in the wash oxidises to the exclusion of the carbon, and vinegar is formed from the remaining or carbonaceous element, which becomes itself slightly oxidised. Thus 2 atoms of alcohol are composed of: —

Carbon	-	4 atoms.
Hydrogen	-	6 „
Oxygen	-	2 „

Digitized by Google

whilst acetic acid acid or pure radical vinegar contains of—

Carbon	4	atoms.
Hydrogen	3	„
Oxygen	3	„

If, therefore, we suppose the contact of air with alcohol to have led to the absorption of oxygen, so as to have oxidised three atoms of hydrogen, and thus produced three atoms of water, we have left —

Carbon	4	atoms.
Hydrogen	3	„
Oxygen	2	„

which, by the mere absorption of another atom of oxygen, becomes—

Carbon	4	atoms.
Hydrogen	3	„
Oxygen	3	„

or pure acetic acid, with which the water produced from the hydrogen remains in union and forms vinegar. From the above it follows that, as the oxidisation of the hydrogen generates heat, there ought to be a very appreciable rise in the temperature during the passage of the wort through the acetifier. And, in practice, this is found to be the case; so that precautions are needed to prevent the heat from rising so high as to vaporise the remaining alcohol of the wash. The temperature sought to be obtained is about 90° to 92° F., at which oxidation goes on freely, and the loss of alcohol is moderate. In using the word moderate, we speak practically rather than chemically; for in reality the loss is very serious with strong worts. From practical results, conducted with more than ordinary care, it has been ascertained that about one-third of all the extractive matter of the malt and grain is lost or dissipated during the processes of fermentation and acetification. Thus, a wort having a specific gravity of 1·072, or, in technical language, weighing about 26 lbs. per barrel, affords vinegar containing 5·4 per cent. of pure acetic acid, and a residuary extract of 10 lbs. from 36 gallons. The former of these would indicate 35 lbs. of sugar, or 13·7 lbs. per barrel of gravity; whilst the latter shows 3·8 lbs. per barrel; the two united being only 17·5 lbs. instead of 26, the original weight. The loss, therefore, has been 8·5 lbs., or from a specific gravity of 1·072 to less than 1·050. This prodigious destruction of extract seems to imply that great improvements may yet take place in the manufacture of vinegar.

The manufacture of vinegar, by Ham's process, is an extremely interesting operation, and when conducted with proper care furnishes results of the most satisfactory and uniform character. These, however, are not to be obtained without a vast amount of experience and the most vigilant attention on the part of the manufacturer. Thus a difference in the water, in the malt, in the mode of washing, in the cooling of the wort, or in the fermentation of the wort, will each give rise to modifications in the acetifying process which no subsequent skill or labour can rectify. There seems no doubt that the most important points in Ham's method are the cooling and fermentation of the wort; though, where perfection is sought for, no one of the other conditions can be omitted or neglected with impunity. We shall, therefore, proceed to treat of these conditions *seriatim*, rather than in the order of their importance. At first sight it might be supposed that the purer the water the better; that is to say, the less the amount of earthy or saline constituents the more valuable the water would be for making vinegar. Experience, however, teaches us the contrary; and science confirms the truth of this teaching, by pointing out the real nature of the operation. When pure water is made to act at a high temperature upon the ordinary ingredients of a vinegar-maker's mash tun, it is not alone the sugar, gum, and starch of the grain which enters into solution, for under such circumstances the gluten is also dissolved; but this gluten is composed of vegetable albumen and vegetable gelatine, the former of which, as is well known, is capable of being decomposed and precipitated by many earthy and metallic salts, of which the sulphate of lime is one. If, therefore, this salt exists in the water employed for the fabrication of vinegar, or of ale or beer, the wort will contain little or no vegetable albumen; consequently, the vinegar or beer made with such water never becomes cloudy or ropy, as happens when pure water is used, for these defects arise from an excess of albuminous matter. The water used for making the celebrated Burton ale contains a great deal of sulphate of lime; and the spring water of Worcester, which is employed by the extensive firm of Hill, Evans, and Co., in that city, vinegar-makers, contains also a very large amount of sulphate of lime, and no doubt contributes much towards maintaining the well-established reputation of that firm. Whenever, therefore, much

Digitized by Google

sulphate of lime exists in water, without the presence of any noxious ingredient, such water may always be relied upon as favourable for the production of good beer and vinegar.

As regards the malt, or rather the mixture of malt and grain, employed for the production of wort, the common Scotch distillers' formula is the best, containing, as it always does, a considerable per-centage of oats, for the long husk of the oat greatly facilitates the operation of draining, and thus secures the thorough separation of the wort from the spent grains.

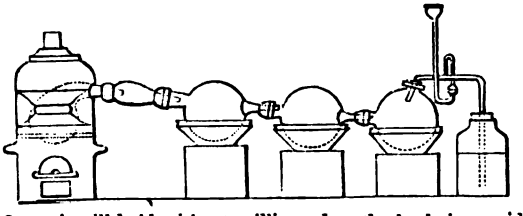
In practice it is found necessary to ferment only two gravities, a high and a low, all the other qualities of vinegar being made by mixing or diluting these after acetification. The most common, and unquestionably the best, gravity for fermentation is that which in technical language weighs about 20 lbs., or has a specific gravity of 1·056 ; the other, or that intended for strong or proof vinegar, being of specific gravity 1·072 : this latter affords a vinegar containing about 5½ per cent. of anhydrous acetic acid.

In every instance the fermentation must be carried to its utmost limit, or to zero at least; and in cooling the wort prior to fermentation, great care must be used to prevent the accession of the acetous fermentation before the yeast is added; for if this happens to any considerable extent, the nitrogenised matter of the yeast is then permanently retained in solution by the acetic acid, and this may give rise to the inconvenience called the "mother." To secure a perfect vinegar by Ham's process, as much attention is required during the cooling and fermentation as for the finest ale; and this axiom cannot be too strongly inculcated into the minds of vinegar-makers. The heat of the fermenting tun should not exceed 75° F., as the alcohol formed by the process is apt at higher temperatures to pass off in considerable quantity with the carbonic acid, and thus give rise to a loss of vinegar. Presuming that the fermentation has been well conducted, and that the specific gravity of the wash is as low as water, or 1·000, the next step is to pass it through that apparatus which constitutes the great peculiarity of Ham's process. This apparatus is called the acetifier.—*Ure.*

C. — *Manufacture of Acetic Acid from Acetate of Copper.*

Before the process for pyroligneous acid, or wood vinegar, was known, there was only one method of obtaining strong vinegar practised by chemists; and it is still followed by some operators, to prepare what is called radical or aromatic vinegar. This consists in decomposing, by heat alone, the crystallised binacetate of copper, commonly, but improperly, called distilled verdigris. With this view, we take a stoneware retort (*fig.* 8), of a size suited to the quantity we wish to operate upon, and coat it with a mixture of fireclay and horsedung, to make it stand the heat better. When this coating is dry, we introduce into the retort the crystallised acetate slightly bruised, but very dry; we fill it as far as it will hold without spilling when the beak is considerably inclined. We then set it in a proper furnace. We attach to its neck an adopter pipe, and two or three globes with opposite tubulures, and a last globe with a vertical tubulure. The apparatus is terminated by a Welter's tube, with a double branch; the shorter issues from the last globe, and the other dips into a flask filled with distilled vinegar. Every thing being thus arranged, we lute the joinings with a putty made of pipeclay and linseed oil, and cover them with glue paper. Each globe is placed in a separate basin of cold water, or the whole may be put into an oblong trough, through which a constant stream of cold water is made to flow. The tubes must be allowed a day to dry. Next day we proceed to the distillation, tempering the heat very nicely at the beginning, and increasing it by very slow degrees till we see the drops follow each other pretty rapidly from the neck of the retort, or the end of the adopter tube. The vapours which pass over are very hot, whence a series of globes are necessary to condense them. We should renew, from time to time, the water of the basins, and keep moist pieces of cloth upon the globes; but this demands great care, especially if the fire be a little too brisk, for the vessels become, in that case, so hot, that they would infallibly be broken if touched suddenly with cold water. It is always easy for us to regulate this operation according to the emission of gas from the extremity

8



Digitized by Google

of the apparatus. When the air bubbles succeed each other with great rapidity, we must damp the fire.

The liquor which passes in the first half hour is weakest; it proceeds, in some measure, from a little water sometimes left in the crystals, which, when well made, however, ought to be anhydrous. A period arrives towards the middle of the process when we see the extremity of the beak of the retort, and of the adopter, covered with crystals of a lamellar or needle shape, and of a pale green tint. By degrees these crystals are carried into the condensed liquid by the acid vapours, and give a colour to the product. These crystals are merely some of the cupreous salt forced over by the heat. As the process approaches its conclusion, we find more difficulty in raising the vapours; and we must then augment the intensity of the heat, in order to continue their disengagement. Finally, we judge that the process is altogether finished, when the globes become cold, notwithstanding the furnace is at the hottest, and when no more vapours are evolved. The fire may then be allowed to go out, and the retort to cool.

As the acid thus obtained is slightly tinged with copper, it must be rectified before bringing it into the market. For this purpose we may make use of the same apparatus, only substituting for the stoneware retort a glass one, placed in a sand-bath. All the globes ought to be perfectly clean and dry. The distillation is to be conducted in the usual way. If we divide the product into thirds, the first yields the feeblest acid, and the third the strongest. We could not push the process quite to dryness, because there remain in the last portions certain impurities which would injure the flavour of the acid.

The total acid thus obtained forms nearly one-half of the weight of the acetate employed, and the residuum forms three-tenths; so that about two-tenths of the acid have been decomposed by the heat, and are lost.—*Ure.*

Other metallic acetates may be used instead of the acetate of copper, but with variable results as to the amount of acetic acid which they yield. Acetates which have easily reducible oxides—as those of copper, silver, mercury, lead, &c.—afford a larger proportion of acetic acid; but acetone marsh gas, as well as carbonic oxide and carbonic acid, invariably accompany it. The acetate of silver gives no acetone; whilst those of the alkaline earths yield chiefly acetone or marsh gas, being converted into carbonates. See ACETONE.

Anhydrous Acetic Acid, as made by Gerhardt, is obtained by mixing perfectly dry fused acetate of potash with about half its weight of chloride of benzoyle, and applying a gentle heat; when a liquid distils over, which, after being rectified, has a constant boiling point of 279° F., and is heavier than water, with which it does not mix until after it has been agitated with it for some time. It dissolves at once in hot water forming acetic acid.

Impurities and Adulterations.

In order to prevent the putrefactive change which often takes place in vinegar, when carelessly prepared by the fermentation of malt wine, &c., it was at one time supposed to be necessary to add a small quantity of sulphuric acid. This notion has long since been shown to be false; nevertheless, since the addition of 1 part of sulphuric acid to 1000 of vinegar was permitted by an Excise regulation, and thus the practice has received legal sanction, it is still continued by many manufacturers. So long as the quantity is retained within these limits, and if pure sulphuric acid be used (great care being taken that there is no arsenic present in such oil of vitriol, as is not unfrequently the case in inferior varieties), no danger can ensue from the habit; but occasionally the quantity is much overpassed by dishonest dealers, of whom it is to be hoped there are but few.

Dr. Ure mentions having found by analysis in a sample of vinegar, made by one of the most eminent London manufacturers, with which he supplied the public, no less than 175 grains of the strongest oil of vitriol per gallon, added to vinegar containing only $3\frac{4}{10}$ per cent. of real acetic acid, giving it an apparent strength after all of only 4 per cent., whereas standard commercial vinegar is rated at 5 per cent.

The methods of determining sulphuric acid will be given, once for all, under the head of ACIDIMETRY, and therefore need not be described in every case where it occurs: the same remark applies to hydrochloric acid and others.

Hydrochloric acid is rarely intentionally added to vinegar; but it may accidentally be present when the pyroligneous acid has been purified by Völckel's process. It is detected by the precipitate which it gives with solution of nitrate of silver in the presence of nitric acid.

Nitric acid is rarely found in vinegar. For its method of detection, see NITRIC ACID.

Wine vinegar generally contains tartaric acid and tartrates; but it is purified from them by distillation.

Digitized by Google

Sulphurous acid is occasionally met with in pyroligneous acid. This is recognised by its bleaching action on delicate vegetable colours, and by its conversion, under the influence of nitric acid, into sulphuric acid, which is detected by chloride of barium.

Sulphuretted hydrogen is detected by acetate of lead giving a black colouration or precipitate.

Metallic Salts.—If care be not taken in constructing the worm of the still of silver or earthenware, distilled acetic acid is frequently contaminated with small quantities of metal from the still, copper, lead, tin, &c. These metals are detected by the addition of sulphuretted hydrogen, as is fully discussed under the head of the individual metals. Copper is the most commonly found, and it may be detected in very minute quantities by the blue colour which the solution assumes on being supersaturated with ammonia.

It is not uncommon to add to pyroligneous acid, a little colouring matter and acetic ether, to give it the colour and flavour of wine or malt vinegar; but this can hardly be called an adulteration.

The presence of the products of acetification of cider may be detected by neutralising the vinegar with ammonia, and then adding solution of acetate of lime. Tartrate of lime is, of course, precipitated from the wine vinegar, while the pearly malic acid of the cider affords no precipitate with the lime, but may be detected by acetate of lead, by the glistening pearly scales of malate of lead, hardly soluble in the cold.

Uses of Acetic Acid.

Acetic acid is extensively employed in the arts, in the manufacture of the various acetates, especially those of alumina and iron, so extensively employed in calico printing as mordants, sugar of lead, &c. It is likewise used in the preparation of varnishes, for dissolving gums and albuminous bodies; in the culinary arts, especially in the manufacture of pickles and other condiments; in medicine, externally, as a local irritant, and internally, to allay fever, &c.

For the treatment in cases of poisoning, we refer to Taylor, Pereira, and other medical authorities.—H. M. W.

At present there are about fifty manufacturers of vinegar on the large scale in this country. There was, until 1842, a duty on vinegar of 2*d.* a gallon. This produced 23,842*l.*, showing that nearly 2,900,000 gallons had been charged with the duty. Since the withdrawal of the duty it has not been possible to determine with any degree of exactness the quantity of vinegar which is made annually. It has been computed—and the computation is probably not far from the truth—that 4,000,000 gallons are now made, and one half of this is made by the five principal vinegar-makers who have their works in London.

The imports of vinegar in 1863, were—

	Gallons.	Computed real Value.
From France - - -	42,809	£4,284
Other parts - - - -	7,268	549
Total Imports - -	50,077	£4,833

The average price fixed for the value has been 2*s.* for the French vinegar and 1*s.* 6*d.* for the other sorts. Since July 6, 1856 the duty on all vinegar imported has been 3*d.* per gallon.

That the importation of this article varies considerably is shown by the following statement:—

In 1843 we imported 21,784 gallons; in 1845, 195,967 gallons; and in 1856, 35,516 gallons.

Of the vinegar made in the United Kingdom, the exports to the end of the year 1863, for the previous six years, were—

	Tons.	Declared Value.		Tons.	Declared Value.
1858 - -	1,029	£23,384	1861 - -	1,383	£29,796
1859 - -	1,101	25,674	1862 - -	856	21,733
1860 - -	1,638	34,762	1863 - -	1,599	29,118

ACETIC ETHERS. (*Acetate of Ethyl. Essigäther. Essignaptha. Essigsaures. Æthyloxyd.*)

These are compounds of acetic acid with the alcohol radicals. See ALCOHOL RADICALS and RADICALS CHEMICAL.

ACETIMETER. An apparatus used for determining the strength of vinegar.

ACETIMETRY. *Determination of the Strength of Vinegar.*—If in vinegars we were dealing with mixtures of pure acetic acid and water, the determination of the density might to a certain extent afford a criterion of the strength of the solution; but vinegar, especially that obtained from wine and malt, invariably contains gluten, saccharine, and mucilaginous matters, which increase its density and render this method altogether fallacious.

Digitized by Google

The only accurate means of determining the strength of vinegar is by ascertaining the quantity of carbonate of soda or potash neutralised by a given weight of the vinegar under examination. This is performed by adding to the vinegar a standard solution of the alkaline carbonate of known strength from a bruette, until, after boiling to expel the carbonic acid, a solution of litmus previously introduced into the liquid is distinctly reddened.

The details of this process, which is equally applicable to mineral and other organic acids, will be found fully described under the head of ACIDIMETRY.

Roughly, it may be stated that every 53 grains of the pure anhydrous carbonate of soda, or every 69 grains of carbonate of potassa (*i. e.* one equivalent), correspond to 60 grains of acetic acid ($C^4 H^4 O^4$).*

It is obvious that preliminary examinations should be made to ascertain if sulphuric, hydrochloric, or other mineral acids are present; and, if so, their amount determined, otherwise they will be reckoned as acetic acid.

The British malt vinegar is stated in the London Pharmacopœia to require a drachm (60 grains) of crystallised carbonate of soda (which contains 10 equivalents of water of crystallisation) for saturating a fluid ounce, or 4·46 grains; it contains, in fact, from 4·6 to 5 per cent. of real acetic acid.

The same authorities consider that the purified pyroligneous acid should require 87 grains of carbonate of soda for saturating 100 grains of the acid.

Dr. Ure suggests the use of the bicarbonate of potash. Its atomic weight, referred to hydrogeo as unity, is 100·584, while the atomic weight of acetic acid is 51·563; if we estimate 2 grains of the bicarbonate as equivalent to 1 of the real acid, we shall commit no appreciable error. Hence a solution of the carbonate containing 200 grains in 100 measures will form an acetimeter of the most perfect and convenient kind; for the measures of test liquid expended in saturating any measure—for instance, an ounce or 1000 grains of acid—will indicate the number of grains of real acetic acid in that quantity. Thus, 1000 grains of the above proof would require 50 measures of the acetimetrical alkaline solution, showing that it contains 50 grains of real acetic acid in 1000, or 5 per cent.

Although the bicarbonate of potash of the shops is not absolutely constant in composition, yet the method is no doubt accurate enough for all practical purposes.

The acetimetrical method employed by the Excise is that recommended by Messrs. J. and P. Taylor†, and consists in estimating the strength of the acid by the specific gravity which it acquires when saturated by hydrate of lime. Acid which contains 5 per cent. of real acid is equal in strength to the best malt vinegar, called by the makers No. 24, and is assumed as the standard of vinegar strength, under the denomination of "proof vinegar."‡ Acid which contains 40 per cent. of real acetic acid is, therefore, in the language of the Revenue, 35 per cent. *over proof;* it is the strongest acid on which duty is charged by the acetimeter. In the case of vinegars which have not been distilled, an allowance is made for the increase of weight due to the mucilage present; hence, in the acetimeter sold by Bate, a weight, marked M, is provided, and is used in trying such vinegars. As the hydrate of lime employed causes the precipitation of part of the mucilaginous matter in the vinegar, it serves to remove this difficulty to a certain extent. (*Pereira.*)—H. M. W.

ACETONE, *syn. pyroacetic spirit, mesitic alcohol, pyroacetic ether.* $C^6 H^6 O^2$. A volatile fluid usually obtained by the distillation of the acetates of the alkaline earths. It is also obtained in a variety of operations where organic matters are exposed to high temperature. Tartaric and citric acids yield it when distilled. Sugar, gum, or starch, when mixed with lime and distilled, afford acetone. If crude acetate of lime be distilled, the acetone is accompanied by a small quantity of ammonia and traces of methylamine. The latter is due to the nitrogen contained in the wood; the distillate from which was used in the preparation of the acetate of lime. Crude acetone may be purified by redistilling it in a water-bath. A small quantity of slaked lime should be added previous to distillation, to combine with any acid that may be present. When pure, it forms a colourless mobile fluid, boiling at 133° F. Its density at 18° is 0·7921, at 32° it is 0·8140. The density of its vapour was found by experiment to be 2·00; theory requires 2·01, supposing six volumes of carbon vapour, twelve volumes of hydrogen, and two volumes of oxygen to be condensed to four volumes. When acetone is procured from acetate of lime, two equivalents of the latter are decomposed, yielding one equivalent of acetone, and two equivalents of carbonate of lime. It has been found that a great number of organic acids, when distilled under similar cir-

* In most cases where, in commercial language, mention is made of *real acetic acid*, the hypothetical compound $C^4H^3O^3$ is meant; but it would be better in future always to give the per-centage of acetic acid $C^4H^4O^4$—for the body $C^4H^3O^3$ is altogether hypothetical—never having yet been discovered. See the remarks on Anhydrous Acetic Acid at the commencement of this article.—H. M. W.

cumstances, yield bodies bearing the same relation to the parent acid that acetone does to acetic acid: this fact has caused the word acetone to be used of late in a more extended sense than formerly. The word ketone is now generally used to express a neutral substance derived by destructive distillation from an acid, the latter losing the elements of an equivalent of carbonic acid during the decomposition. Theoretical chemists are somewhat divided with regard to the rational formulæ of the ketones. An overwhelming weight of evidence has been brought by Gerhardt and his followers, to prove that they should be regarded as aldehydes in which an equivalent of hydrogen is replaced by the radical of an alcohol. Thus common acetone ($C^6 H^6 O^2$) is aldehyde ($C^4 H^4 O^2$), in which one equivalent of hydrogen is replaced by methyle, $C^2 H^3$.

Acetone dissolves several gums and resins, amongst others sandarach. Wood spirit, which sometimes, owing to the presence of impurities, refuses to dissolve sandarach, may be made to do so by the addition of a small quantity of acetone.

When treated with sulphuric acid and distilled, acetone yields a hydrocarbon called mesitylene or mesitylole, $C^{18} H^{12}$.—C. G. W.

ACETYL. Two radicals are known by this name, namely, $C^4 H^3$ and $C^4 H^3 O^2$. Their nomenclature has not, as yet, been definitely settled. Some chemists (following Berzelius, who denied the existence of oxidised radicals) regard acetyl $C^4 H^3$ as a radical, the teroxide of which constituted acetic acid. The followers of Gerhardt, on the other hand, consider acetic acid to contain a radical of the formula $C^4 H^3 O^2$. The latter is generally known as acetyl. Dr. Williamson proposes to call it othyl. The hydrocarbon $C^4 H^3$ is now assumed to exists in aldehyde, which can be regarded as formed on the type two atoms of water, thus:—

$$O^2 \left\{ \begin{matrix} C^4 H^3 \\ H. \end{matrix} \right.$$

In the above formula we have 2 atoms of water, in which 1 equivalent of hydrogen is replaced by the non-oxidised radical $C^4 H^3$, which may very conveniently be named aldyle, to recall its existence in aldehyde.—C. G. W.

ACETYLAMINE. ($C^4 H^5 N$.) An oily alkaloid, produced by acting with the oil of olefiant gas (Dutch liquid, or chloride of ethylene) on an alcoholic solution of ammonia. According to M. Natanson, its discoverer, it boils at 424° F. Its density at 59° is 0·975.—C. G. W.

ACHROMATIC, *destitute of colour*. White light consists, as is shown by its decomposition by a prism, of several coloured rays, having different degrees of refrangibility. (See LIGHT.) When, therefore, white light passes through any transparent body, such as a lens, it is liable to this decomposition to a greater or a less extent, and hence colour is produced. This is termed *chromatic aberration*. Many, especially old-fashioned, telescopes exhibit objects surrounded by beautifully coloured fringes. Now the means which have been devised to prevent this are termed achromatic, signifying the *deprivation of colour*.

ACHROMATIC LENS. Hale, in 1733, constructed lenses which did not produce chromatic dispersion. In 1757 Dolland arrived, by a perfectly independent examination, at the same discovery, and published it.

A lens may be regarded as a number of prisms united round a centre; therefore a ray of light falling on a lenticular glass is decomposed, and the rays being of unequal refrangibility, they have on its axis as many foci as there are colours. The images, therefore, of objects which are produced at these points are superimposed, more or less, and the edges fringed with indistinct colours. The least refrangible rays unite at foci further away than the more refrangible; and the object sought for, and attained, by both Hale and Dolland, was the means of uniting these rays at one focal point. They combined flint-glass with crown-glass, and found that, by a suitable curvature given to the object-glasses, the images seen through them were distinct, and free from these adventitious colours.

Telescopes, microscopes, &c., fitted up with such combinations of lenses as those described, are called achromatic telescopes.

ACID. (*Acidus*, sour, *L.*) The term acid was formerly applied to bodies which were sour to the taste, and in popular language the word is still so used. It is to be regretted that the necessities of science have led to the extension of this word to any bodies combining with bases to form salts, whether such combining body is sour or otherwise. Had not the term *acid* been established in language as expressing a sour body, there would have been no objection to its use; but chemists now apply the term to substances which are not sour, and which do not change blue vegetable colours; and consequently they fail to convey a correct idea to the *popular* mind.

Hobbes, in his "Computation or Logic," says, "A name is a word taken at pleasure to serve for a mark which may raise in our mind a thought like to some thought we had before, and which, being pronounced to others, may be to them a sign of what thought the speaker had, or had not, before in his mind." This philosopher thus truly

Digitized by Google

expresses the purpose of a name; and this purpose is not fulfilled by the term, *acid*, as now employed.

Mr. John Stuart Mill, in his "System of Logic," thus, as it appears not very happily, endeavours to show that the word *acid*, as a scientific term, is not inappropriate or incorrect.

"Scientific definitions, whether they are definitions of scientific terms, *or of common terms used in a scientific sense*, are almost always of the kind last spoken of: their main purpose is to serve as the landmarks of scientific classification. And, since the classifications in any science are continually modified as scientific knowledge advances, the definitions in the sciences are also constantly varying. A striking instance is afforded by the words acid and alkali, especially the former. As experimental discovery advanced, the substances classed with acids have been constantly multiplying; and, by a natural consequence, the attributes connoted by the word have receded and become fewer. At first it connoted the attributes of combining with an alkali to form a neutral substance (called a salt), being compounded of a base and oxygen, causticity to the taste and touch, fluidity, &c. The true analysis of muriatic acid into chlorine and hydrogen caused the second property, composition from a base and oxygen, to be excluded from the connotation. The same discovery fixed the attention of chemists upon hydrogen as an important element in acids; and more recent discoveries having led to the recognition of its presence in sulphuric, nitric, and many other acids, where its existence was not previously suspected, there is now a tendency to include the presence of this element in the connotation of the word. But carbonic acid, silica, sulphurous acid, have no hydrogen in their composition; that property cannot, therefore, be connoted by the term, unless those substances are no longer to be considered acids. Causticity and fluidity have long since been excluded from the characteristics of the class by the inclusion of silica and many other substances in it; and the formation of neutral bodies by combination with alkalis, together with such electro-chemical peculiarities as this is supposed to imply, are now the only *differentia* which form the fixed connotation of the word acid as a term of chemical science."

The term ALKALI, though it is included by Mr. J. S. Mill in connection with *acid* in his remarks, does not stand, even as a scientific term, in the objectional position in which we find acid. *Alkali* is not, strictly speaking, a common name to which any definite idea is attached. *Acid*, on the contrary, is a word *commonly* employed to signify sour. The highest chemical authorities, following Gerhardt, now define ACIDS to be *Salts of Hydrogen*. An acid must now be defined to be a body which has the power of destroying more or less completely the characteristic properties of alkalis—at the same time losing their own distinguishing peculiarities. See ALKALI; ANHYDRIDES.

In this Dictionary all the acids named will be found under their respective heads, as ACETIC, NITRIC, SULPHURIC Acids, &c.

ACIDIFIER. Any body whose presence appears to be necessary for the production of an acid.

ACIDIMETER. An instrument for measuring the strength or quantity of real acid contained in a free state in liquids. The construction of that instrument is founded on the principle that the quantity of real acid present in any sample is proportional to the quantity of alkali which a given weight of it can neutralise. The instrument, like the alkalimeter (see ALKALIMETER), is made to contain 1000 grains in weight of pure distilled water, and is divided accurately into 100 divisions, each of which therefore represents 10 grains of pure distilled water; but as the specific gravity of the liquids which it serves to measure may be heavier or lighter than pure water, 100 divisions of such liquids are often called 1000 grains' measure, irrespectively of their weight (specific gravity), and accordingly 10—20 &c. divisions of the acidimeter are spoken of as 100—200 &c. grains' measure; that is to say, as a quantity or measure which, if filled with pure water, would have weighed that number of grains.

ACIDIMETRY. Acidimetry is the name of a chemical process of analysis by means of which the strength of acids — that is to say, the quantity of pure free acid contained in a liquid — can be ascertained or estimated. The principle of the method based upon Dalton's law of chemical combinations; or, in other words, upon the fact that, in order to produce a complete reaction, a certain definite weight of reagent is required.

If, for example, we take 1 equivalent, or 49 parts in weight, of pure oil of vitriol of specific gravity 1·8485, dilute it (of course within limits) with no matter what quantity of water, and add thereto either soda, potash, magnesia, ammonia, or their carbonates, or in fact any other base, until the acid is neutralised — that is to say, until blue litmus-paper is no longer, or only very faintly, reddened when moistened with a drop of the acid liquid under examination,—it will be found that the respective weights of

Digitized by Google

each base required to produce that effect will greatly differ, and that with respect to the bases just mentioned these weights will be as follows: —

Soda (caustic)	1 equiv.	= 31 parts in weight	} Saturate or neutralise 1 eqv. = 49 parts in weight of pure oil of vitriol (sp. gr. 1·8485), or 1 equiv. of any other acid.
Potash (caustic)	„	= 47 „	
Ammonia	„	= 17 „	
Carbonate of soda	„	= 53 „	
Carbonate of potash	„	= 69 „	

This being the case, it is evident that if we wish to ascertain by such a method the quantity of sulphuric acid or of any other acid contained in a liquid, it will be necessary, on the one hand, to weigh or measure accurately a given quantity of that liquid to be examined, and, on the other hand, to dissolve in a known *volume* of water the *weight* above mentioned of any one of the bases just alluded to, and to pour that solution gradually into that of the acid until neutralisation is obtained; the number of volumes of the basic solution which will have been required for the purpose will evidently indicate the amount in weight of acid which existed in the liquid under examination. Acidimetry is therefore exactly the reverse of alkalimetry, since in principle it depends on the number of volumes of a solution of a base diluted with water to a definite strength, which are required to neutralise a known weight or measure of the different samples of acids.

The solution containing the *known weight* of base, and capable therefore of saturating a *known weight* of acid, is called a "test-liquor;" and an aqueous solution of ammonia, of a standard strength, as first proposed by Dr. Ure, affords a most exact and convenient means of effecting the purpose, when gradually poured from a graduated dropping-tube or acidimeter into the sample of acid to be examined.

The strength of the water of ammonia used for the experiment should be so adjusted that 1000 grains' measure of it (that is, 100 divisions of the alkalimeter) really contain one equivalent (17 grains) of ammonia, and consequently neutralise one equivalent of any one real acid. The specific gravity of the pure water of ammonia employed as a test for that purpose should be exactly 0·992, and when so adjusted, 1000 grains' measure (100 divisions of the acidimeter) will then neutralise exactly

40	grains,	or one	equivalent,	of sulphuric acid (dry).
49	„	„	„	oil of vitriol, sp. gr. 1·8485.
37·5	„	„	„	hydrochloric acid (gas, dry).
54	„	„	„	nitric acid (dry).
60	„	„	„	crystallised acetic acid.
45	„	„	„	oxalic acid.
150	„	„	„	tartaric acid.
51	„	„	„	acetic acid.

And so forth with the other acids.

A standard liquor of ammonia of that strength becomes, therefore, a universal acidimeter, since the number of measures or divisions used to effect the neutralisation of 10 or of 100 grains of any one acid, being multiplied by the atomic weight or equivalent number of the acid under examination, the product, divided by 10 or by 100, will indicate the per-centage of real acid contained in the sample. The proportion of free acid being thus determined with precision, even to $\frac{1}{50}$th of a grain, in the course of five minutes, as will be shown presently.

The most convenient method of preparing the standard liquor of ammonia of that specific gravity is by means of a glass bead, not but that specific-gravity bottles and hydrometers may, of course, be employed; but Dr. Ure remarks, with reason, that they furnish incomparably more tedious and less delicate means of adjustment. The glass bead, of the gravity which the test-liquor of ammonia should have, floats, of course, in the middle of such a liquor at the temperature of 60° F.; but if the strength of the liquor becomes attenuated by evaporation, or its temperature increased, the attention of the operator is immediately called to the fact, since the difference of a single degree of heat, or the loss of a single hundredth part of a grain of ammonia per cent., will cause the bead to sink to the bottom—a degree of precision which no hydrometer can rival, and which could not otherwise be obtained, except by the troublesome operation of accurate weighing. Whether the solution remains uniform in strength is best ascertained by introducing into the bottle containing the ammonia test-liquor two glass beads, so adjusted that one, being very slightly heavier than the liquid, may remain at the bottom; whilst the other, being very slightly lighter, reaches the top, and remains just under the surface as long as the liquor is in the normal state; but when, by the evaporation of some ammonia, the liquor becomes weaker, and consequently its specific gravity greater, the bead at the bottom rises towards the surface, in which case a few drops of strong ammonia should be added to restore the balance.

Digitized by Google

An aqueous solution of ammonia, of the above strength and gravity, being prepared, the acidimetrical process is in every way similar to that practised in alkalimetry; that is to say, a known weight, for example, 10 or 100 grains of the sample of acid to be examined are poured into a sufficiently large glass vessel, and diluted, if need be, with water, and a little tincture of litmus is poured into it, in order to impart a distinct red colour to it; 100 divisions, or 1000 grains' measure, of the standard ammonia test-liquor above alluded to, are then poured into an alkalimeter (which, in the present case, is used as an acidimeter), and the operator proceeds to pour the ammonia test-liquor from the alkalimeter into the vessel containing the acid under examination, in the same manner, and with the same precautions used in alkalimetry (see ALKALIMETRY), until the change of colour, from red to blue, of the acid liquor in the vessel indicates that the neutralisation is complete and the operation finished.

Let us suppose that 100 grains in weight of a sample of sulphuric acid, for example, have required 61 divisions (610 water-grains' measure) of the acidimeter for their complete neutralisation, since 100 divisions (that is to say, a whole acidimeter full) of the test-liquor of ammonia is capable of neutralising exactly 49 grains — one equivalent — of oil of vitriol, of specific gravity 1·8485, it is clear that the 61 divisions employed will have neutralised 29·89 of that acid, and, consequently, the sample of sulphuric acid examined contained that quantity per cent. of pure oil of vitriol, representing 24·4 per cent. of pure anhydrous sulphuric acid: thus —

Divisions. Oil of Vitriol.

100 : 49 :: 61 : x = 29·89.

Anhydrous Acid.

100 : 40 :: 61 : x = 24·4.

The specific gravity of an acid of that strength is 1·2178.

In the same manner, suppose that 100 grains in weight of hydrochloric acid have required 90 divisions (900 grains' measure) of the acidimeter for their complete neutralisation, the equivalent of dry hydrochloric acid gas being 36·5, it is clear that since 90 divisions only of the ammonia test-liquor have been employed, the sample operated upon must have contained per cent. a quantity of acid equal to 33·30 of dry hydrochloric acid gas in solution, as shown by the proportion:—

Divis. Hydrochloric acid.

100 : 36·5 :: 90 : x = 32·85.

The specific gravity of such a sample would be 1·1646.

Instead of the ammonia test-liquor just alluded to, it is clear that a solution containing one equivalent of any other base — such as, for example, carbonate of soda, or carbonate of potash, caustic lime, &c. — may be used for the purpose of neutralising the acid under examination. The quantity of these salts required for saturation will of course indicate the quantity of real acid, and, by calculation, the per-centage thereof in the sample, thus: — The equivalent of pure carbonate of soda 53, and that of carbonate of potash 69, either of these weights will represent one equivalent, and consequently 49 grains of pure oil of vitriol, 36·5 of dry hydrochloric acid, 60 of crystallised, or 51 of anhydrous acetic acid, and so on. The acidimetrical assay is performed as follows:—

If with *carbonate of soda*, take 530 grains of pure and dry carbonate of soda, obtained by igniting the bicarbonate of that base (see ALKALIMETRY), and dissolve them in 10,000 water-grains' measure (1000 acidimetrical divisions) of distilled water. It is evident that each acidimeter full (100 divisions) of such a solution will then correspond to one equivalent of any acid, and accordingly if the test-liquor of carbonate of soda be poured from the acidimeter into a weighed quantity of any acid, with the same precautions as before, until the neutralisation is complete, the number of divisions employed in the operation will, by a simple rule of proportion, indicate the quantity of acid present in the sample as before. Pure carbonate of soda is easily obtained by recrystallising once or twice the crystals of carbonate of soda of commerce, and carefully washing them. By heating them gradually they melt, and at a very low red heat entirely lose their water of crystallisation and become converted into pulverulent anhydrous neutral carbonate of soda, which should be kept in well closed bottles.

When *carbonate of potash* is used, then, since the equivalent of carbonate of potash is 69, the operator should dissolve 690 grains of it in the 10,000 grains of pure distilled water, and the acidimeter being now filled with this test-liquor, the assay is carried on again precisely in the same manner as before. Neutral carbonate of potash for acidimetrical use is prepared by heating the bicarbonate of that base to redness, in order to expel one equivalent of its carbonic acid; the residue left is pure neutral carbonate of potash; and in order to prevent its absorbing moisture, it should be put,

Digitized by Google

whilst still hot, on a slab placed over concentrated sulphuric acid, or chloride of calcium, under a glass bell, and, when sufficiently cool to be handled, transferred to bottles carefully closed.

To adapt the above methods to the French weights and measures, now used also generally by the German chemist, we need only substitute 100 decigrammes for 100 grains, and proceed with the graduations as already described.

A solution of *caustic lime* in cane sugar has likewise been proposed by M. Peligot for acidimetrical purposes. To prepare such a solution, take pure caustic lime, obtained by heating Carara marble among charcoal in a furnace; when sufficiently roasted to convert it into quicklime, slake it with water, and pour upon the slaked lime as much water as is necessary to produce a milky liquor; put this milky liquor in a bottle, and add thereto, *in the cold*, a certain quantity of pulverised sugar-candy; close the bottle with a good cork, and shake the whole mass well. After a certain time it will be observed that the milky liquid has become very much clearer, and perhaps quite limpid; filter it, and the filtrate will be found to contain about 50 parts of lime for every 100 of sugar employed. The liquor should not be heated, because saccharate of lime is much more soluble in cold than in hot water, and if heat were applied it would become turbid or thick, though on cooling it would become clear again.*

A concentrated solution of lime in sugar being thus obtained, it should now be diluted to such a degree that 1000 water-grains' measure of it may be capable of saturating exactly one equivalent of any acid, which is done as follows:—Take 100 grains of hydrochloric acid of specific gravity 1·1812, that weight of acid contains exactly one equivalent = 36·5 of pure hydrochloric acid gas; on the other hand, fill the acidimeter up to 0 (zero) with the solution of caustic lime in sugar prepared as abovesaid, and pour the contents into the acid until exact neutralisation is obtained, which is known by testing with litmus-paper in the usual manner already described. If the whole of the 100 divisions of the acidimeter had been required exactly to neutralise the 100 grains' weight of hydrochloric acid of the specific gravity mentioned, it would have been a proof that it was of the right strength; but suppose, on the contrary, that only 50 divisions of the lime solution in the acidimeter have been sufficient for the purpose, it is evident that it is half too strong, or, in other words, one equivalent of lime (=28) is contained in those 50 divisions instead of in 100. Pour, therefore, at once, 50 divisions or measures of that lime-liquor into a glass cylinder accurately divided into 100 divisions, and fill up the remaining 50 divisions with water; stir the whole well, and 100 divisions of the lime-liquor will, of course, now contain as much lime as was contained before in the 50; or, in other words, 100 acidimetrical divisions will now contain 1 equivalent of lime, and therefore will be capable of exactly neutralising 1 equivalent of any acid.

When, however, saccharate of lime is used for the determination of sulphuric acid, it is necessary to dilute it considerably, for otherwise a precipitate of sulphate of lime would be produced. This reagent, moreover, is evidently applicable only to the determination of such acids the lime salts of which are soluble in water.

Instead of a solution of caustic lime in sugar, a clean dry piece of white Carara marble may be used. Suppose, for example, that the acid to be assayed is acetic acid, the instructions given by Brande are as follows:—A clean dry piece of marble is selected and accurately weighed; it is then suspended by a silk thread into a known quantity of the vinegar or acetic acid to be examined, and which is cautiously stirred with a glass rod, so as to mix its parts, but without detaching any splinters from the weighed marble, till the whole of the acid is saturated, and no further action on the marble is observed. The marble is then taken out, washed with distilled water, and weighed; the loss in weight which it has sustained may be considered as equal to the quantity of acetic acid present, since the atomic weight of carbonate of lime (=50) is very nearly the same as that of acetic acid (=51). Such a process, however, is obviously less exact than those already described.

But, whichever base is employed to prepare the test-liquor, it is clear that the acid tested with it must be so far pure as not to contain any other free acid than that for which it is tested, for in that case the results arrived at would be perfectly fallacious. Unless, therefore, the operator has reason to know that the acid, the strength of which has to be examined by that process, is genuine of its kind, he must make a qualitative analysis to satisfy himself that it is so; for in the contrary case the acid would not be in a fit state to be submitted to an acidimetrical assay.

The strength of acids may also be ascertained by determining either the *volumes* or the *weight* of carbonic acid gas disengaged from pure bicarbonate of soda by a given weight of any acid.

For *measuring* exactly the volumes of carbonic acid thus expelled, Dr. Ure's appa-

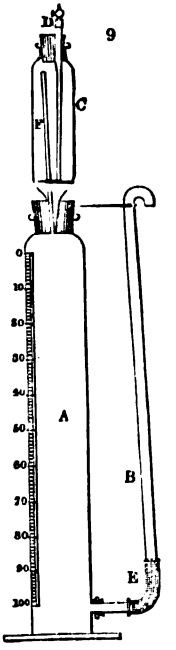
* The directions given by M. Violette for the preparation of Saccharate of Lime are as follow:—Digest in the cold 50 grammes of slaked caustic lime in 1 litre of water containing 100 grammes of sugar.

Digitized by Google

ratus, represented in the figure, may be used. As it is absolutely requisite, for the success of the experiment, that the whole of the acid taken for examination should be completely saturated, the operator must accordingly take care to use a little more bicarbonate than is necessary for the purpose.

Now the equivalent number of bicarbonate of soda is 75, and the carbonic acid contained therein = 44; that of oil of vitriol is 49; wherefore by mixing together 75 grains of pure bicarbonate of soda with 49 grains of pure oil of vitriol, 44 grains of carbonic acid gas will be expelled, equal in bulk or volume to 2381 acidimetrical divisions (23,810 water-grains' measure). These proportions, however, would be inconvenient, the more especially as the acidimeter in question should contain exactly 10,000 water-grains' measure, marked in series of 10 divisions from 0 (zero) at the top down to 100, such an arrangement at once enabling the operator to read off the amount of real acid *per cents.*; and accordingly a weight, or proportion of acid capable of disengaging exactly 10,000 water-grains' measure of carbonic acid from a quantity of bicarbonate more than sufficient to supersaturate it is used. That weight or portion varies, of course, with each kind of acid, thus:—

For anhydrous sulphuric acid it is	- -	16·80 grains.
„ Oil of vitriol - - - -	-	20·58 „
„ Anhydrous nitric acid - - -	-	22·67 „
„ „ hydrochloric acid	- -	15·33 „
„ „ acetic acid - -	-	21·42 „
„ Crystallised citric acid - -	-	80·64 „
„ „ tartaric acid - -	-	63·00 „



Therefore by taking, of any sample of acid to be examined, the exact number of grains corresponding to each of the above-mentioned acids, we shall obtain a volume of carbonic acid gas proportioned to the strength and purity of the sample of each of them respectively. The *modus operandi* is as follows:—Charge the glass cylinder A with water, and pour upon the surface of the latter a layer of olive oil, about 1 inch in thickness, so that the level corresponds exactly to the 0 (zero) of the graduated scale etched on the glass cylinder. Through the cork in the mouth of the cylinder, push the taper tail of the flask, C, air-tight; introduce into this flask C about 50 grains of bicarbonate of soda, in powder, and pour upon them a little more water than is sufficient to cover the powder; and if, for example, the object is to determine the amount of pure oil of vitriol contained in a given sample of that acid, weigh now accurately 20·58 grains of that sample, dilute it with water, and suck it up into the taper dropping-glass tube, D; shut the stopcock, introduce the dropping-tube, pushing it air-tight through the perforated cork until its extremity plunges into the mixture of bicarbonate of soda and water in the flask, C. On opening now slightly the stopcock of the dropping-tube, the acid contained therein coming in contact with the bicarbonate will cause the evolution of a volume of carbonic acid proportioned to its strength. Supposing the same sample of sulphuric acid which was found by the acidimetrical process first described to contain 29·89 of oil of vitriol, or 24·4 of anhydrous sulphuric acid, per cent., to be now examined by the present method, it will be found that the 20·58 grains of that acid taken for the experiment have disengaged a volume of carbonic acid gas corresponding nearly to the number 30 of the graduated scale of the glass cylinder, thereby indicating nearly 30 per cent. of pure oil of vitriol in the sample under consideration.

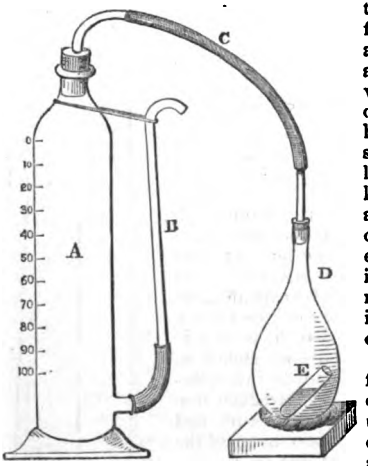
In the same manner the sample of hydrochloric acid, which by the former process was found to contain 32·85 per cent. of pure hydrochloric acid, would now disengage a volume of carbonic acid gas which would depress the level of the water in the glass cylinder nearly to the point marked 33, and therefore the operator would at once know that the quantity of pure hydrochloric acid gas contained in the sample was a little less than 33 per cent., a degree of accuracy quite sufficient for all commercial purposes, and which might besides be rendered still more accurate by lengthening the glass cylinder and diminishing its bore, so that the divisions may be sufficiently distant as to admit of being subdivided into fractions.

The principal objection to this form of acidimeter, however, is its expense, and also the difficulty or trouble of introducing into it *the whole* of the accurately weighed quantity of acid, a circumstance which renders it less applicable to acidimetry than to alkalimetry. By suppressing, however, the top flask, C, and using instead of it a

Digitized by Google

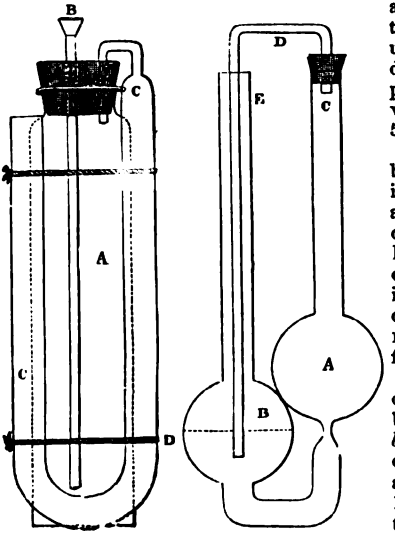
common Florence flask, connected with the cylinder, the cost is considerably reduced, and the operator is at once enabled to secure the complete reaction of the whole of the accurately weighed acid upon the bicarbonate of soda. The arrangement has, besides, several other advantages, which the simple inspection of the annexed figure renders apparent. It consists of a 10,000 water-grains'-measure glass cylinder, A, graduated in the same manner, and provided with a discharge tube, B, as before; but the mouth of the cylinder need not be larger than that of an ordinary wine bottle, which allows of its being corked air-tight with greater ease and certainty. This cork is perforated, and provided with a tube passing air-tight through it, and connected — by a length of vulcanised india-rubber, C — with the disengagement tube of an ordinary Florence flask, into which the bicarbonate of soda and a certain quantity of water has been previously introduced, and likewise a small test-tube, E, containing the exactly weighed quantity of acid to be examined. All the joints being perfectly air-tight, if the Florence flask be now carefully tilted on one side, a portion of the acid in the test-tube will, of course, flow down upon the bicarbonate of soda, and a corresponding quantity of carbonic acid gas being evolved will depress the water in the glass cylinder, causing an overflow from the tube B, which should be held over a basin, and progressively lowered so as to keep the discharging aperture on a level with the descending water in the cylinder. The operation is terminated when, all the acid in the test-tube having been completely upset and all effervescence being entirely at an end, the level of the water in the cylinder A remains stationary; the number of divisions of the scale corresponding to that level are then read off; they indicate the per-centage strength of the sample.

10



The bicarbonate of soda of commerce frequently contains some neutral carbonate of soda, which should be removed before using it for that and for the following process; this is easily done by washing it with a moderate quantity of *cold* water, which dissolves the neutral carbonate, but leaves the greater portion of the bicarbonate in an undissolved state; it should then be dried spontaneously by spreading it in the air, and then kept in stoppered bottles; for though bicarbonate of soda does not undergo decomposition by exposure to dry air, a moist atmosphere converts a portion of it into a neutral carbonate, with 5 equivalents of water (NaO, CO^2 5HO).

11 12



Acidimetrical operations may likewise be performed by determining the *weight* instead of the volumes of the carbonic acid expelled from bicarbonate of potash, or of soda, by a given quantity of acid. For this purpose either of the apparatus contrived by Dr. Ure, and represented in the margin, may be used. The details of their construction are given in ALKALIMETRY, to which the reader is referred.

Since 1 equivalent of any acid will disengage 2 equivalents (= 44) of carbonic acid from 1 equivalent (= 75) of *bicarbonate* of soda, it is evident that by determining what quantity of any pure acid is capable of disengaging or expelling 10 grains of carbonic acid gas, then taking that quantity of the acid to be

Digitized by Google

examined, and causing it to react upon a mass of bicarbonate of soda more than sufficient to saturate or neutralise it (in order to make sure that the acid has produced all its effect), the loss sustained after the operation from the carbonic gas expelled, multiplied by ten, will at once indicate the exact per-centage of real acid contained in the sample examined. Of course the weight of acid capable of disengaging exactly 10 grains of carbonic acid gas varies with each kind of acid; and that weight is found by dividing 10 times the atomic weight of the acid, whatever it may be, by 44; that is to say, by the atomic weight of the two equivalents of carbonic acid gas contained in the bicarbonate of soda.

For sulphuric acid, for example, the proportion would be as follows: —

$$2\,CO^2 \quad SO^3$$
$$44 : 40 :: 10 : x$$
$$x = 9{\cdot}09 \text{ (or more correctly, } 9{\cdot}1).$$

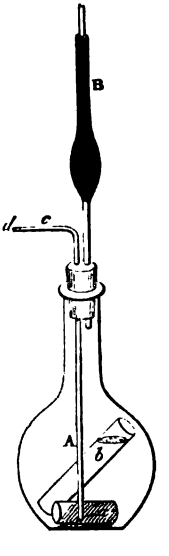
Applying this rule, the weights to be taken are as follows, in reference to —

Dry sulphuric acid - - - - -	9·1
„ nitric acid - - - - -	12·27
„ hydrochloric acid - - -	8·29
„ acetic (dry) - - - -	11·59
Crystallised tartaric acid - - -	34·09
„ citric acid - - -	43·64

Each of these quantities of real acid, with 25 or 26 grains of bicarbonate of soda, will give off 10 grains of carbonic acid gas; and hence, by adding a cypher, that is, multiplying by ten, whatever weight the apparatus loses denotes the per-centage of acid in the sample under trial, without the necessity of any arithmetical reduction. Let us suppose, for example, that the apparatus, being charged with 9·1 grains of a sample of sulphuric acid, is found, after the experiment, to have lost 7·5 grains; this multiplied by 10 = 75·0; therefore the sample contained 75 per cent. of dry sulphuric acid. If the apparatus had lost 2·44 grains thus, it would have indicated 24·4 per cent. of dry or anhydrous acid. Persons accustomed to the French metrical system may use decigrammes instead of grains, and they will arrive at the same per-centage results.

Another apparatus for ascertaining the weight of carbonic expelled for the purposes of either acidimetry or alkalimetry, and which the operator himself may readily construct, is represented in *fig.* 13.

13



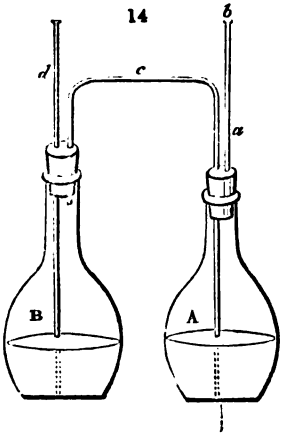
A is a small matrass, with a somewhat wide mouth, capable, however, of being hermetically closed by a cork perforated with two holes, through one of which a bulbous tube, B, passes filled with fragments of chloride of calcium; through the other hole a tube, *c*, is introduced, sufficiently long to reach the bottom of the matrass A.

A certain quantity (say 25 grains) of bicarbonate of soda, greater than is required for saturation, is then introduced into the matrass A, and likewise enough water to cover it. A small glass test-tube is next charged with the proper quantity of the acid to be examined, namely, 9·1 if for sulphuric acid, 12·27 if for nitric acid, &c. &c., as before-mentioned, and it is carefully introduced into the matrass A, taking care that the acid does not come in contact with the bicarbonate of soda, which is easily avoided by lowering the tube containing the acid into the matrass with a thread, or by carefully sliding it down, and keeping it nearly in an upright position, leaning against the sides of the matrass, as shown by the letter *b*. The matrass is then to be closed with the cork provided with its tubes, as above directed, and the whole is accurately weighed. This done, the apparatus is gently jerked, or tilted, on one side, so as to cause a portion of the acid in the tube *b* to flow among the bicarbonate of soda on which it is resting. A disengagement of carbonic acid gas immediately takes place from the decomposition of the carbonate of soda by the acid. When the violent effervescence has subsided, a fresh quantity of acid is again jerked, or spilled, out of the tube, until the whole of the acid is emptied, the tube occupying now a horizontal position, as represented by letter A. The water, which is mechanically carried off by the carbonic acid, is arrested by the chloride of calcium of the bulbous tube B. When all disengagement of carbonic acid gas has ceased, even after shaking the apparatus, the residuary

Digitized by Google

gas is sucked up through the bulbous tube B, while the atmospheric air enters at the orifice, *d*, of the bent tube, *c*, to replace it. If the apparatus has become warm during the reaction, it should be allowed to cool completely, and it is then weighed again accurately. The difference between the first and second weighing, the loss represents, of course, the weight of the carbonic acid gas expelled, and consequently the per-centage of real acid contained in the sample.

Instead of the preceding arrangement, the apparatus contrived by Drs. Fresenius and Will may be used. The figure in the margin at once renders the construction



of that apparatus intelligible, and as a full description of it is given in the article on ALKALIMETRY, the reader is accordingly referred thereto. When that contrivance is used for acidimetrical purposes, proceed as follows:—Fill bottle A with ordinary oil of vitriol to about one-half of its capacity, and pour into bottle B the accurately weighed quantity of acid to be examined, namely, 9·1 grains for sulphuric acid, 12·27 for nitric acid, &c. &c., according to the rule and table given (page 29), and dilute it with water, so that bottle B may be one-third full. Put now into a test-tube a quantity of bicarbonate of soda sufficient to saturate the weight of acid contained in bottle B, and suspend it into that bottle by means of a thread, kept tight by the pressure of the cork. Weigh now the whole apparatus accurately; this done, carefully loosen the thread, so that the test-tube charged with bicarbonate of soda may fall into the acid, and the cork being instantly adjusted air-tight, the whole of the carbonic acid gas disengaged is led by tube *c* into the concentrated sulphuric acid of bottle A, which absorbs all its moisture before it finally escapes through the tube *a*. When all effervescence has ceased, the operator, by applying his lips to that tube *a*, sucks out all the residuary carbonic acid gas contained in the apparatus, and replaces it by atmospheric air, which enters at *d*. The apparatus, if it have become warm, should be allowed to cool completely, and on weighing it again the loss indicates the per-centage of real acid present in the sample.

The balance used in these methods should, of course, be sufficiently delicate to indicate small weights when heavily laden.

We shall terminate this article by a description of Liebig's acidimetrical method of determining the amount of prussic acid contained in solutions; for example, in medicinal prussic acid, in laurel and bitter-almond water, essence of bitter almonds, and cyanide of potassium. The process is based upon the following reaction:—When an excess of caustic potash is poured in a solution which contains prussic acid, cyanide of potassium is, of course, formed; and if nitrate of silver be then poured in such a liquor, a precipitate of cyanide of silver is produced, but it is immediately redissolved by shaking, because a double cyanide of silver and of potassium (Ag Cy + K Cy) is formed, which dissolves, without alteration, in the excess of potash employed. The addition of a fresh quantity of nitrate of silver produces again a precipitate which agitation causes to disappear as before; and this reaction goes on until *half* the amount of prussic acid present in the liquor has been taken up to produce cyanide of silver, the other *half* being engaged with the potassium in the formation of a double cyanide of silver and of potassium, as just said. As soon, however, as this point is reached, any new quantity of nitrate of silver poured in the liquor causes the cyanide of potassium to react upon the silver of the nitrate, to produce a *permanent* precipitate of cyanide of silver, which indicates that the reaction is complete, and that the assay is terminated. The presence of chlorides, far from interfering, is desirable, and a certain quantity of common salt is accordingly added, the reaction of chloride of silver being analogous to that of the cyanide of the same metal.

To determine the strength of prussic acid according to the above process, a test or normal solution should be first prepared, which is as follows:—

Since 1 equivalent of nitrate of silver (=170) represents, as we have seen, 2 equivalents of prussic acid (=54), dissolve, therefore, 170 grains of pure fused nitrate of silver in 10,000 water-grains' measure of pure water; 1000 water-grains' measure (1 acidimeter full) of such solution will therefore contain 17 grains of nitrate of silver, and will therefore represent 5·4 grains of prussic acid; and consequently each acidimetrical division 0·054 grain of pure prussic acid.

Digitized by Google

Take now a given weight or measure of the sample of prussic acid, or cyanide of potassium, or laurel, or bitter-almond water, or essence of bitter almonds; dilute it with three or four times its volume of water, add caustic potash until the whole is rendered alkaline, and carefully pour into it a certain quantity of the normal silver solution from the acidimeter until a slight precipitate begins to appear which cannot be redissolved by agitation; observe the number of acidimetrical divisions of the test silver solution employed, and that number multiplied by 0·054 will, of course, indicate the proportion of prussic acid present in the quantity of the sample operated upon.

For such liquids which, like laurel-water, contain very little prussic acid, it is advisable to dilute the test silver liquor with nine times its bulk of water; a decimal solution is thus obtained, each acidimetrical division of which will only represent 0·0054 of prussic acid, by which figure the number of divisions employed should then be multiplied.

As the essence of bitter almonds mixed with water is turbid, it is absolutely necessary to add and shake it with a sufficient quantity of water to dissolve the particles of oil to which the milkiness is due, and render it quite clear.

Instead of an acidimeter, an ordinary balance may be used as follows:—Take 63 grains of fused nitrate of silver, and dissolve them in 5937 grains weight of pure distilled water, making altogether 6000 grains weight of test silver solution. Weigh off now in a beaker any quantity, say 100, or, if very weak, 1000 grains' weight of the sample of prussic acid to be examined, dilute it with three or four times its bulk of water, mix with it a certain quantity of a solution of common salt, and a few drops of caustic potash over and above the quantity necessary to make it alkaline. Pour now carefully into the liquor so prepared a portion of the test solution of silver alluded to, until a turbidness or milkiness begins to be formed which does not disappear by agitation, and which indicates that the reaction is complete. Every 300 grains of the test silver solution employed represents 1 grain weight of pure anhydrous prussic acid.

The rationale of these numbers is evident: since 1 equiv. = 170 of nitrate of silver correspond to 2 equiv. = 54 of prussic acid; 63 of nitrate of silver correspond to 20 of prussic acid, and consequently 300 of a solution containing 63 of nitrate of silver in 6000 correspond to 1 of prussic acid thus:—

170 : 54 :. 63 : 20
6000 : 20 :: 300 : 1

Lastly, the strength of prussic acid may also be determined with an ordinary balance by a method proposed by Dr. Ure, which method, however, is much less convenient than that of Liebig; it consists in adding peroxide of mercury, in fine powder, to the liquor which contains prussic acid, until it ceases to be dissolved. As the equivalent of peroxide of mercury = 108, is exactly four times that of prussic acid = 27, the weight of peroxide of mercury employed divided by four will give the quantity of prussic acid present.*—A. N. See SULPHYDROMETRY.

ACIPENSER. A genus of cartilaginous fishes, to which the Sturgeon belongs, and from which isinglass is obtained. See ISINGLASS.

ACONITINE. $C^{60}\,H^{47}\,NO^{14}$. A poisonous alkaloid constituting the active principle of the Aconite, *Aconitum Napellus*.—C. G. W.

ACONITUM. (*ἀκόνιτον*.) The Greek name for the Hemlock, a genus of plants belonging to the *Ranunculaceæ*, nearly all the species being remarkable for their poisonous properties.

ACORNS. The seed of the oak (*quercus*). These possess some of the properties of the bark, but in a very diluted degree. Acorns are now rarely used. Pigs are sometimes fed upon them.

ACORUS CALAMUS. The common sweet flag. This plant is a native of England, growing abundantly in the rivers of Norfolk, from which county the London market is chiefly supplied. The *radix calami aromatica* of the shops occurs in flattened pieces about one inch wide and four or five inches long. It is employed medicinally as an aromatic, and it is said to be used by some distillers to flavour gin. The essential oil (*oleum acori calami*) of the sweet flag is used by snuff-makers for scenting snuff, and it sometimes enters as one of the aromatic ingredients of aromatic vinegar.—*Pereira.*

ACROSPIRE. (*Plumule*, Fr.; *Blattkeim*, Germ.). The sprout at the end of seeds when they begin to germinate. Malsters use the name to express the growing of the barley. "The first leaves that appear when corn sprouts."—*Lindley.*

ACRYLAMINE, or ALLYLAMINE. ($C^6\,H^7\,N$.) A new alkaloid obtained by

Hofmann and Cahorns, by boiling cyanate of allyle with a strong solution of potash. It boils at about 365°.—C. G. W.

ACTINISM. (From ἀκτὶν, a ray; signifying merely the *power* of a ray, without defining what character of ray is intended.)

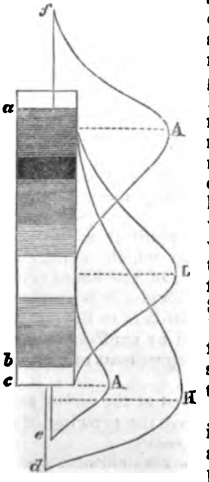
As early as 1812, M. Berard (in a communication to the Academy of Sciences, on some observations made by him of the phenomena of solar action) drew attention to the fact, that three very distinct sets of physical powers were manifested. Luminous power, Heat-producing power, and Chemical power. Chaptal, Berthollet, and Biot reported on this paper by M. Berard; and, as showing the extent to which this very important inquiry had proceeded in the hands of this philosoper, the following quotation is given from their report.

"M. Berard found that the chemical intensity was greatest at the violet end of the spectrum, and that it extended, as Ritter and Wollaston had observed, a little beyond that extremity. When he left substances exposed for a certain time to the action of each ray, he observed sensible effects, though with an intensity continually decreasing, in the indigo and blue rays. Hence we must consider it as extremely probable, that if he had been able to employ reactions still more sensible, he would have observed analogous effects, but still more feeble, even in the other rays. To show clearly the great disproportion which exists in this respect between the energies of different rays, M. Berard concentrated, by means of a lens, all that part of the spectrum which extends from *the green to the extreme violet*, and he concentrated, by another lens, all that portion which extends from the *green to the extremity of the red ray*. This last pencil formed a white point, so brilliant that the eyes were scarcely able to endure it, yet the muriate of silver remained exposed more than two hours to this brilliant point of light, without undergoing any sensible alteration. On the other hand, when exposed to the other pencil, which was much less bright and less hot, it was blackened in less than six minutes. * * * * * If we wish to consider solar light as composed of three distinct substances, one which occasions *light*, another *heat*, and the third *chemical combinations*, it will follow that each of those substances is separable by the prism into an infinity of different modifications, like Light itself; since we find, by experiment, that each of the three properties, *chemical*, *calorific*, and *colourific*, is spread, though unequally, over a certain extent of the spectrum. Hence we must suppose, on that hypothesis, that there exists *three spectrums* one above another; namely, a calorific, a colourific, and a chemical spectrum."

This was the earliest indication of the probable existence of a physical force, in the solar rays, distinct from Light and Heat. A large number of philosophers still hold to the idea that the chemical changes produced by the sunbeam are due to *light*, and this idea is confirmed in the public mind by the universal adoption of the term *photography* (light-drawings) to indicate the production of pictures by the agency of the sunbeam. See PHOTOGRAPHY.

The actual conditions of the sunbeam will be understood by reference to the annexed woodcut, and attention to the following description, *fig.* 15: *a b* represents the prismatic spectrum—as obtained by the decomposition of white light by the prism—or Newtonian luminous spectrum, consisting of certain bands of colour. Newton determined those rays to be seven in number; red, orange, yellow, green, blue, indigo, and violet; recent researches, by Sir John Herschel and others, have proved the existence of two other rays; one, the extreme red or crimson ray *c*, found at the least refrangible end of the spectrum, the other occurring at the most frangible end, or beyond the violet rays, which is a lavender or grey ray. Beyond this point up to *f*, Professor Stokes has discovered a new set of rays, which are only brought into view when the light is received upon the surfaces of bodies which possess the property of altering the refrangibility of the rays. Those rays have been called the *fluorescent rays*, from the circumstance that some of the varieties of Fluor Spar exhibit this phenomenon in a remarkable manner. (See FLUORESCENCE.) The curved line L from *a* to *c* indicates the full extent of the luminous spectrum, the point marked L showing the maximum of illuminating power, which exists in the yellow ray.

15



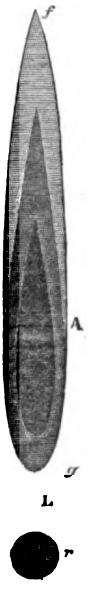
Sir William Herschel and Sir Henry Englefield determined, in the first instance, the maximum point for the calorific rays, and Sir John Herschel subsequently confirmed their results, proving that the greatest heat was found below the red ray, and that it gradually diminished in power with the increase of refrangibility in the

Digitized by Google

rays, ceasing entirely in the violet ray. Heat rays have been detected down to the point *d*, and the curved line H indicates the extent of their action.

Now, if any substance capable of undergoing chemical change be exposed to this spectrum, the result will be found to be such as is represented in the accompanying figure and *fig.* 16. Over the space upon which the greatest amount of light falls, *i.e.* the region of the yellow and orange rays L, no chemical change is effected: by prolonged action a slight change is brought about where the red ray falls, *r*, but from the mean green ray G up to the point *f*, a certain amount of chemical action is maintained; the maximum of action being in the blue and violet rays A. Thus the curve line (*fig.* 15) from *e* to *f* represents the extent and degree of chemical power as manifested in the solar spectrum. Two maxima are marked A A, differing widely however in their degree.

16



Here, as in Berard's experiments, we see that where the *light* is the strongest, there is no chemical action, and that as the luminous power diminishes the chemical force is more decidedly manifested.

Again, we find that if we take a piece of yellow glass, stained with oxide of silver, we have a medium which entirely prevents the permeation of the chemical rays, though it obstructs no Light. But, if a very dark blue glass is taken, we find that ninety per cent. of the luminous rays are obstructed, while the chemical rays permeate it most freely. Numerous experiments of an analogous character appear to prove that the chemical and luminous powers of the sunbeam are balanced against each other (see Hunt's "Researches on Light"), that they are indeed antagonistic principles or powers. That there are three very distinct sets of phenomena, every one admits.

Light (*luminous power*), to which belongs the phenomena of vision and the production of colour.

Heat (*calorific power*), the function of which appears to be the determining the physical condition of all matter, as regards its solid, fluid, or gaseous condition.

Actinism (*chemical power*), to which all the phenomena of photography are due, and many of the more remarkable changes observed in the vegetable kingdom.

ACTINOGRAPH. A name given to an instrument for recording the variations in the chemical (*actinic*) power of the solar beams. The name signifies *ray writer*.

ACTINOMETER. (*Ray measurer.*) The name of various forms of instruments, the objects of which are to measure the direct heat radiations from the sun. The term has also been applied to instruments employed to measure the varying intensities of Light.

ADDITIONS. Such articles as are added to the fermenting wash of the distiller, were of old distinguished by this trivial name.

ADHESION (*sticking together*). The union of two surfaces. With the phenomena which are dependent upon bringing two surfaces so closely together that the influence of *cohesion* is exerted we have not to deal. In arts and manufactures, adhesion is effected by interposing between the surfaces to be united, some body possessing peculiar properties, such as gum, plaster, resin, marine or ordinary glue, and various kinds of cement. *Adhesion* should be restricted to mean, sticking together by means of some interposed substance; *cohesion*, the state of union effected by natural attraction.

Not only is adhesion exhibited in works of art or manufacture; we find it very strikingly displayed in nature. Fragments of rocks which have been shattered by convulsion are found to be cemented together by silica, lime, oxide of iron, and the like; and broken parts of mineral lodes are frequently reunited by the earthy minerals.

ADIPIC ACID. (C^{12} H^{10} O^{8}.) One of the fixed fatty acids produced by the action of nitric acid on oleic acid, suet, spermaceti, and other fatty bodies. See Watts' "Dictionary of Chemistry."

ADIPOCIRE. From *adeps*, fat; *cera*, wax. (*Adipocire*, Fr.; *Fettwachs*, Germ.) The fatty matter supposed to be generated in dead bodies buried under peculiar circumstances. It is chiefly *margarate of ammonia*. In 1786 and 1787, when the churchyard of the *Innocents*, at Paris, was cleaned out, and the bones transported to the Catacombs, it was discovered that not a few of the *cadavres* were converted into a saponaceous white substance, more especially many of those which had been interred for fifteen years in one pit, to the amount of 1500, in coffins closely packed together. These bodies were flattened in consequence of their mutual pressure; and, though they generally retained their shape, there was deposited round the bones of several a

Digitized by Google

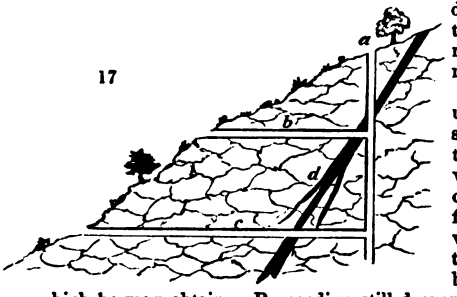
greyish white, somewhat soft, flexible substance. Fourcroy presented to the Academy of Sciences, in 1789, a memoir which appeared to prove that the fatty body was an ammoniacal soap containing phosphate of lime; that the fat was similar to spermaceti, as it assumed, on slow cooling, a foliated crystalline structure; as also to wax, as, when rapidly cooled, it became granular; hence he called it *adipocire*. Its melting point was 52·5° C. (126·5° F.)

This substance was again examined by Chevreul, in 1812, and was found by him to contain margaric acid, oleic acid, combined with a yellow colouring odorous matter, besides ammonia, a little lime, potash, oxide of iron, salts of lactic acid, an azotised substance; and was therefore considered as a combination of margaric and oleic acids, in variable proportions. These fat acids are obviously generated by the reaction of the ammonia upon the margarine and oléine, though they eventually lose the greater part of that volatile alkali. It is sometimes confounded with chlorestine. See FAT and FATTY BODIES.

Bog butter is said to be a similar substance; and ADIPOCIRE is a synonyme of Hatchettine, or rock fat.

ADIPOSE SUBSTANCE or ADIPOSE TISSUE. (*Tissu graisseux*, Fr.) An animal oil, resembling in its essential properties the vegetable oils. During life, it appears to exist in a fluid or semi-fluid state; but, in the dead animal, it is frequently found in a solid form, constituting *suet*, which, when divested of the membrane in which it is contained, is called *tallow*. See TALLOW, OILS, &c.

ADIT, or ADIT LEVEL. The horizontal entrance to a mine; a passage or level driven into the hill-side. The accompanying section gives, for the purpose of distinctness, an exaggerated section of a portion of the subterranean workings of a metalliferous mine. It should be understood that *d* represents a minerallode, upon which the *shaft*, *a*, has been sunk. At a certain depth from the surface of the hill the miners would be inconvenienced by water, consequently a level is *driven* in from the side of the hill, *b*, through which the water flows off, and through which also the miner can bring out the broken rock, or any ores which he may obtain. Proceeding still deeper, supposing the workings to have commenced, as is commonly the case, at a certain elevation above the sea-level, similar conditions to those described again arising, another level is driven so as to intersect the shaft or shafts, as shown at *c*. In this case, *b* would be called the *shallow*, and *c* the *deep* adit. The economy of such works as these is great, saving the cost of expensive pumping machinery, and, in many cases, saving also considerable labour in the removal of ores or other matter from the mine.



The great Gwennap Adit, in Cornwall, with its branches, was cut through the solid rock for nearly 30 miles; through it numerous mines are drained to a certain depth, and the water pumped from greater depths discharged. The Nentforce Level, or Adit, in Alston Moor, has been wrought under the course of the river Nent, and it extends about 3¼ miles into that important mining district. See MINING.

ADULTERATION. The practice of debasing any product of manufacture by the introduction of cheap and often injurious materials.

The extent to which the adulteration of almost every useful article is carried, is at once a disgrace to the trading community, and a standing reflection on an age which boasts of its high moral character.

ADZE. A cutting instrument; differing from the axe by the edge being placed at nearly right angles to the handle, and being slightly curved up or inflected towards it. The instrument is held in both hands, whilst the operator stands upon his work in a stooping position; the handle being from twenty-four to thirty inches long, and the weight of the blade from two to four pounds. The adze is swung in a circular path almost of the same curvature as the blade, the shoulder joint being the centre of motion, and the entire arm and tool forming, as it were, one inflexible radius; the tool, therefore, makes a succession of small arcs, and in each blow the arm of the workman is brought in contact with the thigh, which serves as a stop to prevent accident. In coarse preparatory works, the workman directs his adze through the space between his two feet; he thus surprises us by the quantity of wood removed; in fine works he frequently places his toes over the spot to be wrought, and the adze penetrates two or three inches beneath the sole of the shoe; and he thus surprises us

Digitized by Google

by the apparent danger, yet perfect working of the instrument, which, in the hands of a shipwright in particular, almost rivals the joiner's plane; it is with him the nearly universal paring instrument, and is used upon works in all positions. — *Holtzapffel.*

ÆOLIAN HARP. A musical instrument; the invention of Kircher; although it was probably indicated by Hero of Alexandria. The musical sounds are produced by the action of a current of air upon strings placed above a long box of thin deal. The wires of the electric telegraph on the sides of our railroads are frequently set in such a state of vibration by the wind, that they become gigantic Æolian harps.

AERATED WATER. The common commercial name of water artificially impregnated with carbonic acid or oxygen.

AEROLITES. Meteoric stones. It cannot be denied that masses of solid matter have fallen from the atmosphere upon this earth. Various hypotheses have been proposed to account for them; amongst others the following may be named:—

1. That they are aggregations of solid matter which take place in the higher regions of the air. When we remember that hydrogen gas will *dissolve*, and carry off in an invisible state many of our metals, and that all known metals are volatile under certain conditions of heat, it will be evident that such combinations might take place.

2. That they are projected from volcanoes in the moon. The researches of Nasmyth, Smyth, and others appear to prove that our satellite, whatever may have been her condition at one period, is now in a state of repose; nothing like an active volcano has been discovered on the moon's surface.

3. That belts composed of fragments of matter circulate in certain fixed orbits around the sun, and that these fragments, sometimes entering our atmosphere, are involved in the Earth's influences, and fall in obedience to the law of gravitation. The flights of "shooting stars" which are observed at particular periods appear to favour this view.

It is evident that meteoric stones are of cosmical origin; and the composition, therefore, of such as have been examined, shows us the composition of masses of matter existing beyond the earth. A few analyses of meteoric stones will exhibit the chemical character of these extraordinary masses.

	(1)	(2)	(3)	(4)

—*Brook and Miller.*

A meteorite fell at Dharwar, in the East Indies, on the 15th February, 1848, which gave 58·3 per cent. of silicates insoluble in *aqua regia*; 2·5 of sulphur, 6·76 of nickel, and 22·18 of iron. Another stone from Singhur, near Ponna, in the Deccan, gave earthy silicate, 19·5; iron, 69·16; and nickel, 4·24. Ehrenberg examined a black inky rain-water which fell in Ireland on the 15th of April, 1849, and found the black colour to consist of minute particles of decayed plants, which had probably been brought by the trade winds, and, floating in clouds of aqueous vapour, had decayed.

AËROSTATION; AËRONAUTICS. The ascent into the atmosphere by means of balloons.

The Montgolfier balloon is a bag filled with air which is rarefied by the action of fire; and thus the whole mass is rendered specifically lighter than the surrounding medium.

The investigations of Cavendish led to the use of hydrogen gas—the lightest of known bodies—to inflate silken bags; and since his time our balloons have been inflated with either pure hydrogen, or with common coal gas—carburetted hydrogen.

Notwithstanding the numerous attempts which have been made to navigate the air, nothing has been done to enable the aëronaut to steer his balloon. In whatever current of air he may be, with that current he moves; until this difficulty is overcome, we cannot expect any satisfactory results from aëronautics. Some interesting and useful experiments have been made by using captive balloons, by which we have arrived at some facts connected with the upper regions of the air, which could not be obtained by any other means. See BALLOONS.

ÆRUGO. (*Verdigris; carbonate of copper*, which see.) The name formerly given to the bright green rust, produced by the oxygen of the air and carbonic acid, upon copper, and its alloys bronze and brass. The Romans gave this name; they considered that the ærugo added much to the beauty of their statues; and

Digitized by Google

adjusted the composition of their alloys with the view of producing the finest green colour. This was frequently effected artificially; and to distinguish the real from the artificial they used the term *ærugo nobilis*. This is the *patina* of the Italians; it is the same as verdigris.

ÆTHER. See ETHER.

AFFINITY. The term used by chemists to denote the peculiar attractive Force which produces the combination of dissimilar substances,—as an acid with an alkali, or of sulphur with a metal. See Watts' "Dictionary of Chemistry."

AGAR-AGAR. A seaweed forming a large article of commerce in the East. It is frequently called Bengal Isinglass, from the fact of its being found largely in the Bengal market. It is used for making jellies and for stiffening purposes. See ALGÆ.

AGARICUS. A genus of the order Fungi. Many of this genus—the mushrooms—are used for food. See FUNGI.

AGARIC *of the oak;* called also *surgeon's agaric, spunk, touchwood.* A fungus found growing on the oak, birch, willow, and other trees. See AMADOU.

AGATE. An instrument used by gold-wire drawers, so called from the agate fixed in the middle of it.

AGATE. (*Agate*, Fr.; *Achat*, Gr.; *Achates*, Lat.) A siliceous mineral; a variegated variety of chalcedony.

This stone is the Ἀχάτης of the Greeks, by whom it was so called after the river in Sicily of that name, whence, according to Theophrastus, agates were first procured. Bochart, with much probability, deduces the name from the Punic and Hebrew, *nakad*, spotted.

The colours of agate are either arranged in parallel or concentric bands, or assume the form of clouds or spots, or arborescent and moss-like stains. These colours are due to the presence of metallic oxides, and when indistinct, they are frequently artificially developed or produced. By boiling the colourless stone in oil, and afterwards in sulphuric acid, the oil is absorbed by the more porous layers of the stone; it subsequently becomes carbonised, and thus the contrast of the various colours is heightened. The red varieties, also, are artificially produced by boiling them in a solution of proto-sulphate of iron; after which, upon exposing the stones to heat, peroxide of iron is formed, and thus red bands, or rings, of varying intensities, are produced. Cornelians are thus very commonly formed; the colouring matter of the true stone being a peroxide of iron.

Agates never occur in a crystalline form, but in the form of rounded pebbles; they are translucent by transmitted light, but are not transparent, have a wax-like fracture, and they are susceptible of a brilliant polish.

Agates are used in the arts for inlaying, and for burnishing gold and silver: they are also made into mortars for chemical purposes; and when cut and polished, they are converted, in considerable quantities, into brooches, bracelets, and other ornamental articles.

Agates are brought to this country from Arabia, India, and Oberstein, in Saxony: they are also found in Perthshire, and other parts of Scotland. The Scotch Pebble is a variety of the agate, known by its zigzag pattern as the *Fortification Agate.*

Agates are found frequently in the amygdaloid rocks of Galgenburg, near Oberstein. They are usually ground into form, cut, and polished, at water-mills in the neighbourhood, where a considerable trade in them is carried on.

Moss Agate, or *Mocha Stone*, is a chalcedony, containing within it dendritic or moss-like delineations, of an opaque brownish-yellow colour, which are due to oxide of manganese, or of iron.—H. W. B.

Agates are found in the Canton markets, as articles of commerce, in abundance, and of the following varieties: The white-veined agate, called also Mocha Stone, varies from 1 to 8 inches in diameter. The dull milky agate, not so valuable, occurs in sizes of 1 to 10 inches.

Lead-coloured agate, sometimes uniform, and sometimes spotted, occurs of large size, and is used for cups and boxes. Flesh-coloured. Blood-coloured. This is sometimes variegated with pale-blue and brown; the blue always surrounds the red; the brown has the tint of horn.

Clouded and spotted flesh-coloured agate is found subject to many flaws.

Red agate, with yellow, is of 1 to 4 inches in diameter.

The yellow has various tints. Sometimes the pebbles are 7 inches in length. The yellow agate is used for knife-handles.

The pale-yellow agate is very scarce; it is called also Leonina, being variegated with white, black, and green, and bearing some resembance to a lion's skin.

Blackish-veined brown agate, in pieces from 2 to 7 inches in diameter, is very

Digitized by Google

hard, and is cut into seals, buttons, and heads of canes, &c., with natural veins, or fictitious colours, sunk into the stone. It appears to be of much value, especially when it is found sufficiently large to be formed into mortars for chemical purposes. "The royal collection at Dresden contains a table-service of German agate, and at Vienna, in the Imperial cabinet, there is an oval dish twenty-two inches in length, formed of a single stone."—*Dana.*

Agates, as already stated, may be stained artificially. This is effected sometimes by soaking the stone in a solution of nitrate of silver, and then exposing it to the sun. This colour disappears on laying the stone for a few hours in nitric acid. A knowledge of the practicability of thus staining agates naturally leads to the suspicion that many of the colours are not the work of nature but of art.

The total importations of agates were valued in 1855 at 5,196*l.*, and in 1856 at 7,534*l.* In these returns agates and cornelians in their natural states—as also manufactured but not set - and such as were mounted as jewels, were included. Of late years they have been included under the head of "Precious Stones of the inferior class unset," the computed real value of the importations of these in 1863 being 12,380*l.*

AIR. The gaseous envelope which surrounds this Earth is emphatically so called; it consists of the gases nitrogen and oxygen.

About 79 measures of nitrogen, or azote, and 21 of oxygen, with $\frac{1}{100}$th of carbonic acid, constitute the air we breathe. The term *air* is applied to any permanently gaseous body. And we express different conditions of the air, as *good air*, *bad air*, *foul air*, &c.

AIR, COMPRESSED. For its employment in some mining operations, see MINING.

AIR-ENGINE. The considerable expansibility of air by heat naturally suggested its use as a motive power long before theoretical investigation demonstrated its actual value. The great advance made during the last few years in our knowledge of the mechanical action of heat, has enabled us to determine with certainty the practical result which may be obtained by the use of any contrivance for employing heat as a prime mover of machinery. We are indebted to Professor Wm. Thomson for the fundamental theorem which decides the economy of any thermo-dynamic engine. It is — that in any perfectly constructed engine the fraction of heat converted into work is equal to the range of temperature from the highest to the lowest point, divided by the highest temperature reckoned from the zero of absolute temperature. Thus, if we have a perfect engine in which the highest temperature is 280° and the lowest 80° F., the fraction of heat converted into force will be $\frac{280-80,}{280+460,}$ or rather more than one quarter. So that, if we use a coal of which one pound in combustion gives out heat equivalent to 10,380,000 foot pounds, such an engine as we have just described would produce work equal to 28,05,405 foot pounds for each pound of coal consumed in the furnace. From the above formula of Professor Thomson, it will appear that the economy of any perfect thermo-dynamic engine depends upon the range of temperature we can obtain in it. And as the lowest temperature is generally nearly constant, being ruled by the temperature of the surface of the earth, it follows that the higher we can raise the highest temperature, the more economical will be the engine. The question is thus reduced to this: — In what class of engine can we practically use the highest temperature? In the steam-engine worked with saturated vapour, the limit is obviously determined by the amount of pressure which can be safely employed. In the steam-engine worked with super-heated vapour—*i.e.* in which the vapour, after passing from the boiler, receives an additional charge of heat without being allowed to take up more water—and also in the air-engine, the limit will depend upon the temperature at which steam or air acts chemically upon the metals employed, as well as upon the power of the metals themselves to resist the destructive action of heat. It thus appears that the steam-engine worked with superheated steam possesses most of the economical advantages of the air-engine. But when we consider that an air-engine may be made available where a plentiful supply of water cannot be readily obtained, the importance of this kind of thermo-dynamic engine is incontestable. The merit of first constructing a practical air-engine belongs to Mr. Stirling. Mr. Ericsson has subsequently introduced various refinements, such as the respirator—a reticulated mass of metal, which, by its extensive conducting surface, is able, almost instantaneously, to give its own temperature to the air which passes through it. But various practical difficulties attend these refinements, which, at best, only apply to engines worked between particular temperatures. The least complex engine, and that which would probably prove most effectual in practice, is that described in the "Philosophical Transactions," 1852, Part I. It

Digitized by Google

consists of a pump, which compresses air into a receiver, in which it receives an additional charge of heat; and a cylinder, the piston of which is worked by the heated air as it escapes. The difference between the work produced by the cylinder and that absorbed by the pump constitutes the force of the engine; which, being compared with the heat communicated to the receiver, gives results exactly conformable with the law of Professor Thomson above described.—J. P. J.

Dr. Joule has proposed various engines to be worked at temperatures below redness, which, if no loss occurred by friction or radiation, would realise about one-half the work due to the heat of combustion; or about four times the economical duty which has, as yet, been attained by the most perfect steam-engine.

A detailed account of Ericsson's Calorific Engine may be useful, especially as a certain amount of success has attended his efforts in applying the expansive power of heat to move machinery. It is stated in Hunt's "Merchant's Magazine" that Ericsson's engines are at work in the foundry of Messrs. Hogg and Delamater, in New York; one engine being of five and another of sixty horse power. The latter has four cylinders. Two, of seventy-two inches diameter, stand side by side. Over each of these is placed one much smaller. Within these are pistons exactly fitting their respective cylinders, and so connected, that those within the lower and upper cylinders move together. Under the bottom of each of the lower cylinders a fire is applied, no other furnaces being employed. Neither boilers nor water are used. The lower is called the working cylinder; the upper, the supply cylinder. As the piston in the supply cylinder moves down, valves placed in its top, open, and it becomes filled with cold air. As the piston rises within it, these valves close, and the air within, unable to escape as it came, passes through another set of valves into a receiver, from whence it has to pass into the working cylinder to force up the working piston within it. As it leaves the receiver to perform this duty, it passes through what is called *the regenerator*, where it becomes heated to about 450°; and upon entering the working cylinder, it is further heated by the supply underneath. For the sake of illustration, merely, let us suppose that the working cylinder contains double the area of the supply cylinder: the cold air which entered the upper cylinder will, therefore, but only half fill the lower one. In the course of its passage to the latter, however, it passes through *the regenerator*; and as it enters the working cylinder, we will suppose that it has become heated to about 480°, by which it is expanded to double its volume, and with this increased capacity it enters the working cylinder. We will further suppose the area of the piston within this cylinder to contain 1000 square inches, and the area of the piston in the supply cylinder above to contain but 500. The air presses upon this with a mean force, we will suppose, of about eleven pounds to each square inch; or, in other words, with a weight of 5500 pounds. Upon the surface of the lower piston the heated air is, however, pressing upwards with a like force upon each of its 1000 square inches; or, in other words, with a force which, after overcoming the weight above, leaves a surplus of 5500 pounds, if we make no allowance for friction. This surplus furnishes the working power of the engine. It will be seen that after one stroke of its pistons is made, it will continue to work with this force so long as sufficient heat is supplied to expand the air in the working cylinder to the extent stated; for, so long as the area of the lower piston is greater than that of the upper, and a like pressure is upon every square inch of each, so long will the greater piston push forward the smaller, as a two-pound weight upon one end of a balance will be sure to bear down a one pound weight placed upon the other. We need hardly say, that after the air in the working cylinder has forced up the piston within it, a valve opens; and as it passes out, the pistons, by the force of gravity, descend, and cold air again rushes into and fills the supply cylinder. In this manner the two cylinders are alternately supplied and discharged, causing the pistons in each to play up and down substantially as they do in the steam-engine.

The regenerator must now be described. It has been stated that atmospheric air is first drawn into the supply cylinder, and that it passes through the regenerator into the working cylinder. The regenerator is composed of wire net, like that used in the manufacture of sieves, placed side by side, until the series attains a thickness of about 12 inches. Through the almost innumerable cells formed by the intersections of the wire, the air must pass on its way to the working cylinder. In passing through these it is so minutely divided that all parts are brought into contact with the wires. Supposing the side of the regenerator nearest the working cylinder is heated to a high temperature, the air, in passing through it, takes up, as we have said, about 450° of the 480° of heat required to double the volume of the air; the additional 30° are communicated by the fire beneath the cylinder.

The air has thus become expanded, it forces the piston upwards; it has done its work — valves open, and the imprisoned air, heated to 480°, passes from the cylinder

Digitized by Google

and again enters the regenerator, through which it must pass before leaving the machine. It has been said that the side of this instrument nearest the cylinder is kept hot; the other side is kept cool by the action upon it of the air entering in the opposite direction at each up-stroke of the pistons; consequently, as the air from the working cylinder passes out, the wires absorb the heat so effectually, that when it leaves the regenerator it has been robbed of it all, except about 30°.

The regenerator in the 60-horse engine measures 26 inches in height and width, internally. Each disc of wire composing it contains 676 superficial inches, and the net has 10 meshes to the inch. Each superficial inch, therefore, contains 100 meshes, which, multiplied by 676, gives 67,600 meshes in each disc; and, as 200 discs are employed, it follows that the regenerator contains 13,520,000 meshes; and consequently, as there are as many spaces between the discs as there are meshes, we find that the air within it is distributed in about 27,000,000 minute cells. Thence every particle of air, in passing through the regenerator, is brought into very close contact with a surface of metal which heats and cools it alternately. Upon this action of the regenerator, Ericsson's Calorific Engine depends. In its application on the large scale, contemplated in the great Atlantic steamer called "The Ericsson," the result was not satisfactory. We may, however, notwithstanding this result, safely predicate, from the investigation of Messrs. Thomson and Joule, that the expansion of air by heat will eventually, in some conditions, take the place of steam as a motive power.

AIR-GUN. This is a weapon in which the elastic force of air is made use of to project the ball. It is so arranged, that in a cavity in the stock of the gun, air can be, by means of a piston, powerfully condensed. Here is a reserved force, which, upon its being relieved from pressure, is at once exerted. When air has been condensed to about $\frac{1}{40}$th of its bulk, it exerts a force which is still very inferior to that of gunpowder. In many other respects the air-gun is but an imperfect weapon, consequently it is rarely employed.

AIR-PUMP. A machine by which the air can be exhausted from any vessel containing it. It is employed in scientific investigations for exhibiting many very interesting phenomena in connection with the pressure of air, and its presence or absence; and it is connected with, and forms an important part of, the improved modern steam-engine. Similar machines are also used for condensing atmospheric air; these have been employed on a large scale in some civil engineering purposes.

AIRO-HYDROGEN BLOWPIPE. A blowpipe in which air is used in the place of oxygen, to combine with and give intensity of heat to a hydrogen flame for the purposes of soldering. See AUTOGENOUS SOLDERING.

ALABASTER, *Gypsum*, *Plaster of Paris* (*Albâtre*, Fr.; *Alabaster*, Germ.), a sulphate of lime. (See ALABASTER, ORIENTAL.) When massive, it is called indifferently alabaster or gypsum; and when in distinct and separate crystals, it is termed selenite. Massive alabaster occurs in Britain in the new red or keuper marl: in Glamorganshire, on the Bristol Channel; in Leicestershire, at Syston; at Tutbury and near Burton-on-Trent, in Staffordshire; at Chellaston, in Derbyshire; near Droitwich it is associated in the marl with rock salt, in strata respectively 40 and 75 feet in thickness; and at Northwich and elsewhere the red marl is intersected with frequent veins of gypsum. At Tutbury it is quarried in the open air, and at Chellaston in caverns, where it is blasted by gunpowder: at both places it is burned in kilns, and otherwise prepared for the market. It lies in irregular beds in the marl, that at Chellaston being about 30 feet thick. There is, however, reason to suppose that it was not originally deposited along with the marl as sulphate of lime, but rather that calcareous strata, by the access of sulphuric acid and water, have been converted into sulphate of lime — a circumstance quite consistent with the bulging of the beds of marl with which the gypsum is associated, the lime, as a sulphate, occupying more space than it did in its original state as a carbonate. At Tutbury, and elsewhere, though it lies on a given general horizon, yet it can scarcely be said to be truly bedded, but ramifies among the beds and joints of the marl in numerous films, veins, and layers of fibrous gypsum.

A snow-white alabaster occurs at Volterra, in Tuscany, much used in works of art in Florence and Leghorn. In the Paris basin it occurs as a granular crystalline rock, in the Lower Tertiary rocks, known to geologists as the upper part of the Middle Eocene freshwater strata. It is associated with beds of white and green marls; but in the Thuringewald there is a great mass of sulphate of lime in the Permian strata. It has been sunk through to a depth of 70 feet, and is believed to be metamorphosed magnesian limestone or Zechstein. In the United States this calcareous salt occurs in numerous lenticular masses in marly and sand strata of that part of the Upper Silurian strata known as the Onondaga salt group. It is excavated for agricultural purposes. For mineralogical character, &c., see GYPSUM.— A. C. R.

Digitized by Google

The fineness of the grain of alabaster, the uniformity of its texture, the beauty of its polished surface, and its semi-transparency, are the qualities which render it valuable to the sculptor and to the manufacturer of ornamental toys.

The alabaster is worked with the same tools as marble; and as it is many degrees softer, it is so much the more easily cut; but it is more difficult to polish, from its little solidity. After it has been fashioned into the desired form, and smoothed down with pumice stone, it is polished with a pap-like mixture of chalk, soap, and milk; and, last of all, finished by friction with flannel. It is apt to acquire a yellowish tinge.

Besides the harder kinds, employed for the sculpture of large figures, there is a softer alabaster, pure white and semi-transparent, from which small ornamental objects are made, such as boxes, vases, lamps, stands of time-pieces, &c. This branch of business is much prosecuted in Florence, Leghorn, Milan, &c., and employs a great many turning-lathes. Of all the alabasters, the Florentine merits the preference, on account of its beauty and uniformity, so that it may be fashioned into figures of considerable size; for which purpose there are large workshops where it is cut with steel saws into blocks and masses of various shapes. Other sorts of gypsum, such as that of Salzburg and Austria, contain sand veins, and hard nodules, and require to be quarried by cleaving and blasting operations, which are apt to crack it and render it unfit for all delicate objects of sculpture. It is, besides, of a grey shade, and often stained with darker colours.

The alabaster best adapted for the fine arts is pretty white when newly broken, and becomes whiter on the surface by drying. It may be easily cut with the knife or chisel, and formed into many pleasing shapes by suitable steel tools. It is worked either by the hand alone, or with the aid of a turning-lathe. The turning tools should not be too thin or sharp-edged; but such as are employed for ivory and brass are most suitable for alabaster, and are chiefly used to shave and to scratch the surface. The objects which cannot be turned may be fashioned by the rasping tools, or with minute files, such as variegated foliage. Fine chisels and graving tools are also used for the better pieces of statuary.

For polishing such works, a peculiar process is required: pumice stone, in fine powder, serves to smooth down the surfaces very well, but it soils the whiteness of the alabaster. To take away the unevenness and roughness, dried shave-grass (*equisetum*) answers best. Frictions with this plant and water polish down the asperities left by the chisel: the fine streaks left by the grass may be removed by rubbing the pieces with slaked lime, finely pulverised, sifted, and made into a paste; or with putty-powder (oxide of tin) and water. The polish and satin-lustre of the surface are communicated by friction, first with soap water and lime, and finally with powdered and elutriated talc or French chalk.

Such articles as consist of several pieces are joined by a cement composed of quick-lime and white of egg, or of well-calcined and well-sifted Paris plaster, mixed with the least possible quantity of water.

Alabaster objects are liable to become yellow by keeping, and are especially injured by smoke, dust, &c. They may be in some measure restored by washing with soap and water, then with clear water, and again polished with shave-grass. Grease-spots may be removed either by rubbing with talc powder, or with oil of turpentine.

The surface of alabaster may be etched by covering over the parts that are not to be touched with a solution of wax in oil of turpentine, thickened with white lead, and immersing the articles in pure water after the varnish has set. The action of the water is continued from 20 to 50 hours, more or less, according to the depth to which the etching is to be cut. After removing the varnish with oil of turpentine, the etched places, which are necessarily deprived of their polish, should be rubbed with a brush dipped in finely-powdered gypsum, which gives a kind of opacity, contrasting well with the rest of the surface.

Alabaster may be stained either with metallic solutions, with spiritous tinctures of dyeing plants, or with coloured oils, in the same way as marbles.

The gypsum of our own country is found, in apparently inexhaustible quantities, in the Red Marl formation in the neighbourhood of Derby, and has been worked for many centuries. The great bulk of it is used for making plaster of Paris, and as a manure; and it is the basis of many kinds of cements, patented—as Keene's, Martin's, and others.

To get it for these purposes, it is worked by mining underground, and the stone is blasted by gunpowder; but this shakes it so much as to be unfit for working into ornaments, &c.; to procure blocks for which it is necessary to have an open quarry. By removing the superincumbent marl, and laying bare a large surface of the rock, the alabaster being very irregular in form, and jutting out in several parts, allows of its being *sawn* out in blocks of considerable size, and comparatively sound (as is illus

Digitized by Google

trated by the large tazza in the Museum of Practical Geology). This stone, when protected from the action of water, is extremely durable, as may be seen in churches all over the country, where monumental effigies, many centuries old, are now as perfect as the day they were made, excepting of course wilful injuries; but exposure to rain soon decomposes the stone, and it must be borne in mind that it is perfectly unsuited for garden vases or other out-door work in this country.

In working, it can be sawn up into slabs with toothed saws, and for working mouldings and sculptures, fine chisels, rasps, and files are the implements used; the polishing is performed by rubbing it with pieces of sandstone, of various degrees of fineness, and water until it is quite free from scratches, and then giving a gloss by means of polishing powder (oxide of tin) applied on a piece of cloth, and rubbed with a considerable degree of friction on the stone. This material gives employment in Derby to a good many hands in forming it into useful and ornamental articles, and is commonly called Derbyshire Spar; most of the articles are turned in the lathe, and it works something like very hard wood.

Another kind of gypsum also found in Derbyshire is the fibrous or silky kind; it occurs in thin beds, from one to six inches in depth, and is crystallised in long needle-like fibres; being easily worked, susceptible of a high polish, and quite lustrous, it is used for making necklaces, bracelets, brooches, and suchlike small articles.—S. H.

ALABASTER, ORIENTAL. Oriental alabaster is a form of stalagmitic or stalactitic carbonate of lime, an Egyptian variety of which is highly esteemed. It is also procured from the Pyrenees, from Chili, and from parts of the United States of America. Ancient quarries are still in existence in the province of Oran, in Algeria.

ALBANI STONE. (*Lapis albanus.*) The Peperino of modern geologists. A dark volcanic tufa found in Italy, much used at Rome before building with marble became common. The Italian name *peperino* is derived from *pepe*, pepper, which it somewhat resembles.

ALBATA PLATE, a name given to one of the varieties of white metal now so commonly employed. See COPPER, and ALLOYS.

ALBUM GRÆCUM. The white fæces of dogs. After the hair has been removed from skins, this is used to preserve the softness of them, and prepare them for the tan-pit. Fowls' dung is considered by practical tanners as superior to the dung of dogs, and this is obtained as largely as possible. These excreta may be said to be essentially phosphate of lime and mucus. We are informed that various artificial compounds which represent, chemically, the conditions of those natural ones, have been tried without producing the same good results. It is a reflection on our science, if this is really the case.

ALBUMEN. (*Album Ovi.*) Albumen is a substance which forms a constituent part of the animal fluids and solids, and which is also found in the vegetable kingdom. It exists nearly pure in the white of egg. Albumen consists of:—

Cabron	53·32
Hydrogen	7·29
Nitrogen	15·7
Sulphur	1·3
Oxygen	22·39

its Formula being $S^2 N^{37} C^{216} H^{169} O^{66}$. Albumen coagulates by heat, as is illustrated in the boiling of an egg. The salts of tin, bismuth, lead, silver, and mercury form with albumen white insoluble precipitates; therefore, in cases of poisoning by corrosive sublimate, nitrate of silver. or sugar of lead, the white of egg is the best antidote which can be administered. See ALBUMIN, Watts' "Dictionary of Chemistry."

Albumen is employed for clarifying vinous and syrupy liquids, and in calico-printing.

We imported the following quantities of albumen: in 1862, 1037 cwts., valued at 16,884*l.*; and in 1863, 948 cwts., valued at 12,166*l.*

ALBUMENISED PAPER. A paper prepared with the white of egg for photographic purposes. See PHOTOGRAPHY.

ALCARAZZAS. Porous earthenware vessels made in Spain from a sandy marl, and but slightly fired. They are used for cooling liquors. Those vessels are made in France under the name of *hygroceramen*; similar kinds of earthenware are also manufactured in Staffordshire and Derbyshire.

ALCOHOL. (*Alcool*, Fr.; *Alkohol*, or *Weingeist*, Germ.) The word *alcohol* is derived from the Hebrew word "*kohol*," כחל *to paint*. The oriental females were and are still in the habit of painting the eyebrows with various pigments; the one generally employed was a preparation of antimony, and to this the term was generally applied. It became, however, gradually extended to all substances used for the purpose, and ultimately to

Digitized by Google

strong spirits, which were employed, probably, as solvents for certain colouring principles. The term was subsequently exclusively used to designate ardent spirits, and ultimately the radical or principle upon which their strength depends.

As chemistry advanced, *alcohol* was found to be a member only of a class of bodies agreeing with it in general characters; and hence the term is now generic, and we speak of the various *alcohols*. Of these, common or vinous alcohol is the best known; and, in common life, by "alcoholic liquors," we invariably mean those containing the original or vinous alcohol.

When the characters of ordinary alcohol have been stated, allusion will be made to the class of bodies of which this is the type.

Fermented liquors were known in the most remote ages of antiquity. We read (Genesis ix.) that after the flood "Noah planted a vineyard, and he drank of the wine and was drunken." Homer, who certainly lived 900 years before the Christian era, also frequently mentions wine, and notices its effects on the body and mind (Odyssey IX. and XXI.); and Herodotus tells us that the Egyptians drank a liquor fermented from barley. The period when fermented liquors were submitted to distillation, so as to obtain "*ardent spirits*," is shrouded in much obscurity. Raymond Lully* was acquainted with "spirits of wine," which he called *aqua ardens*. The separation of absolute alcohol would appear to have been first effected about this period (1300), by Arnauld de Villeneuve, a celebrated physician residing in Montpellier (*Gerhardt*), and its analysis was first performed by Th. de Saussure.†

The preparation of alcohol may be divided into three stages:—

1. The production of a fermented vinous liquor — the Fermentation.
2. The preparation from this of an ardent spirit — the Distillation.
3. The separation from this ardent spirit of the last traces of water — the Rectification.

1. *Fermentation.* The term "fermentation" is now applied to those mysterious changes which vegetable (and animal) substances undergo when exposed, at a certain temperature, to contact with organic or even organised bodies in a state of change.

There are several bodies which suffer these metamorphoses, and under the influence of a great number of different exciting substances, which are termed the "ferments;" moreover, the resulting products depend greatly upon the temperature at which the change takes place.

The earliest known and best studied of these processes is the one commonly recognised as the *vinous* or *alcoholic fermentation.*

In this process solutions containing *sugar* — either the juice of the grape (see WINE) or an infusion of germinated barley, malt, (see BEER) — are mixed with a suitable quantity of a ferment; beer or wine yeast is usually employed (see YEAST), and the whole maintained at a temperature of between 70° and 80° F. (21° to 26° C.)

Other bodies in a state of putrefactive decomposition will effect the same result as the yeast, such as putrid blood, white of egg, &c.

The liquid swells up, a considerable quantity of froth collects on the surface, and an abundance of gas is disengaged, which is ordinary carbonic acid (CO^2). The composition of (pure) alcohol is expressed by the formula $C^4 H^6 O^2$, and it is produced in this process by the breaking up of an equivalent of *grape sugar*, $C^{24} H^{28} O^{28}$, into 4 equivalents of alcohol, 8 of carbonic acid, and 4 of water —

$$\begin{array}{rl} C^{24}\ H^{28}\ O^{28} & \\ \underline{C^{16}\ H^{24}\ O^{24}} & = 4\ (C^4\ H^6\ O^2) \\ C^8\ H^4\ O^{28} & \\ \underline{H^4\ O^4} & = 4\ HO \\ C^8 \quad O^{24} & = 8\ CO^2 \end{array}$$

It is invariably the *grape sugar* which undergoes this change; if the solution contains cane sugar, the cane sugar is first converted into grape sugar under the influence of the ferment. See SUGAR.

Much diversity of opinion exists with respect to the office which the ferment performs in this process, since it does not itself yield any of the products. See FERMENTATION.

The liquid obtained by the vinous fermentation has received different names, according to the source whence the saccharine solution was derived. When procured from the expressed juice of fruits — such as grapes, currants, gooseberries, &c. — the product is denominated *wine*; from a decoction of malt, *ale* or *beer*; from a mixture of honey and water, *mead*; from apples, *cider*; from the leaves and small branches of

* Thomson's History of Chemistry, i. 41. (1830)

† Annales de Chimie, xlii. 225.

Digitized by Google

the spruce-fir (*abies excelsa*, &c.), together with sugar or treacle, *spruce*; from rice, *rice beer* (which yields the spirit *arrack*); from cocoa-nut juice, *palm wine*.

It is an interesting fact that alcohol is produced in very considerable quantities (in the aggregate) during the raising of bread. The carbonic acid which is generated in the dough, and which during its expulsion raises the bread, is one of the products of the fermentation of the sugar in the flour, under the influence of the yeast added; and of course at the same time the complementary product, alcohol, is generated. As Messrs. Ronalds and Richardson remark*: "The enormous amount of bread that is baked in large towns — in London, for instance, 8·8 millions of cwts. yearly — would render the small amount of alcohol contained in it of sufficient importance to be worth collecting, provided this could be done sufficiently cheaply." In London it has been estimated that in this way about 300,000 gallons of spirit are annually lost; but the cost of collecting it would far exceed its value.

2. *Distillation*. By the process of *distillation*, *ardent spirits* are obtained, which have likewise received different names according to the sources whence the fermented liquor has been derived: viz. that produced by the distillation of wine being called *brandy*, and in France *cognac*, or *eau de vie*; that produced by the distillation of the fermented liquor from sugar and molasses, *rum*. There are several varieties of spirits made from the fermented liquor procured from the cereals (and especially barley), known according to their peculiar methods of manufacture, flavour, &c. — as *whisky*, *gin*, *Hollands* — the various *compounds* and *liqueurs*. In India, the spirit obtained from a fermented infusion of rice is called *arrack*.

3. *Rectification*; preparation of *absolute alcohol*. It is impossible by distillation alone to deprive spirit of the whole of the water and other impurities — to obtain, in fact, *pure* or *absolute* alcohol.

This is effected by mixing with the liquid obtained after one or two distillations, certain bodies which have a powerful attraction for water. The agents commonly employed for this purpose are quicklime, carbonate of potash, anhydrous sulphate of copper, or chloride of calcium. Perhaps the best adapted for the purpose, especially where large quantities are required, is quicklime; it is powdered, mixed in the retort with the spirit (previously twice distilled), and the neck of the retort being securely closed, the whole left for 24 hours, occasionally shaking; during this period the lime combines with the water, and then on carefully distilling, avoiding to continue the process until the last portions come over, an alcohol is obtained which is free from water. If not quite free, the same process may be again repeated.

In experiments on a small scale, an ordinary glass retort may be employed, heated by a water-bath, and fitted to a Liebig's condenser cooled by ice-water, which passes lastly into a glass receiver, similarly cooled.

Although alcohol of sufficient purity for most practical purposes can be readily obtained, yet the task of procuring absolute alcohol entirely free from a trace of water, is by no means an easy one.

Mr. Drinkwater † effected this by digesting ordinary alcohol of specific gravity ·850 at 60° F. for 24 hours with carbonate of potash previously exposed to a red heat; the alcohol was then carefully poured off and mixed in a retort with as much fresh-burnt quicklime as was sufficient to absorb the whole of the alcohol; after digesting for 48 hours, it was slowly distilled in a water-bath at a temperature of about 180° F. This alcohol was carefully redistilled, and its specific gravity at 60° F. found to be ·7947, which closely agrees with that given by Gay-Lussac as the specific gravity of absolute alcohol. He found, moreover, that recently ignited anhydrous sulphate of copper was a less efficient dehydrating agent than quicklime.

Graham recommends that the quantity of lime employed should never exceed three times the weight of the alcohol.

Chloride of calcium is not so well adapted for the purification of alcohol, since the alcohol forms a compound with this salt.

Many other processes have been suggested for depriving alcohol of its water.

A curious process was proposed many years ago by Soëmmering ‡, which is dependent upon the peculiar fact, that whilst water moistens animal tissues, alcohol does not, but tends rather to abstract water from them. If a mixture of alcohol and water be enclosed in an ox bladder, the water gradually traverses the membrane and evaporates, whilst the alcohol does not, and consequently by the loss of water the spirituous solution becomes concentrated.

This process, though an interesting illustration of exosmose, is not practically applicable to the production of anhydrous alcohol; it is, however, an economical method,

and well suited for obtaining alcohol for the preparation of varnishes. Smugglers, who bring spirits into France in bladders hid about their persons, have long known, that although the liquor decreased in bulk, yet it increased in strength; hence the people preferred the article conveyed clandestinely. Professor Graham has ingeniously proposed to concentrate alcohol as follows:—

"A large shallow basin is covered, to a small depth, with recently burnt quicklime, in coarse powder, and a smaller basin, containing three or four ounces of commercial alcohol, is made to rest upon the lime; the whole is placed under the low receiver of an air-pump, and the exhaustion continued till the alcohol evinces signs of ebullition. Of the mingled vapours of alcohol and water which now fill the receiver, the quicklime is capable of uniting with the aqueous only, which is therefore rapidly withdrawn, while the alcohol vapour is unaffected; and as water cannot remain in the alcohol as long as the superincumbent atmosphere is devoid of moisture, more aqueous vapour rises, which is likewise abstracted by the lime, and thus the process goes on till the whole of the water in the alcohol is removed. Several days are always required for this purpose."

Properties of Alcohol.—Absolute.

In the state of purity, alcohol is a colourless liquid, highly inflammable, burning with a pale blue flame, very volatile, and having a density of 0·792 at 15·5° C. (60° F.) (*Drinkwater.*) It boils at 78·4° C. (173° F.) It has never yet been solidified, and the density of its vapour is 1·6133.

Anhydrous alcohol is composed by weight of 52·18 carbon, 13·04 hydrogen, and 34·78 of oxygen. It has for its symbol $C^4 H^6 O^2 = C^4 H^5 O + HO$, or hydrated oxide of ethyle. It has a powerful affinity for water, removing the water from moist substances with which it is brought in contact. In consequence of this property, it attracts water from the air, and rapidly becomes weaker, unless kept in very well-stopped vessels. In virtue of its attraction for water, alcohol is very valuable for the preservation of organic substances, and especially of anatomical preparations, in consequence of its causing the coagulation of albuminous substances; and for the same reason it causes death when injected into the veins.

When mixed with water a considerable amount of heat is evolved, and a remarkable contraction of volume is observed. These effects being greatest with 54 per cent. of alcohol and 46 of water, and thence decreasing with a greater proportion of water. For alcohol which contains 90 per cent. of water, this condensation amounts to 1·94 per cent. of the volume; for 80 per cent., 2·87; for 70 per cent., 3·44; for 60 per cent., 3·73; for 40 per cent., 3·44; for 30 per cent., 2·72; for 20 per cent., 1·72; for 10 per cent., 0·72.

Alcohol is prepared absolute for certain purposes, but the mixtures of alcohol and water commonly met with in commerce are of an inferior strength. Those commonly sold are "Rectified Spirit," and "Proof Spirit."

"Proof Spirit" is defined by Act of Parliament, 58 Geo. III. c. 28, to be "such as shall, at the temperature of fifty-one degrees of Fahrenheit's thermometer, weigh exactly twelve-thirteenth parts of an equal measure of distilled water." And by very careful experiment, Mr. Drinkwater has determined that this proof spirit has the following composition:—

Alcohol and Water.		Specific Gravity at 60° F.	Bulk of the mixture of 100 measures of Alcohol, and 81·82 of Water.
By weight.	By measure.		
Alcohol Water.	Alcohol. Water.		
100 + 103·09			
49·100 + 50·76	100 + 81·82	·919	175·25

Spirit which is weaker is called "under proof;" and that stronger, "above proof." The origin of these terms is as follows:—Formerly a very rude mode of ascertaining the strength of spirits was practised, called the *proof*; the spirit was poured upon gunpowder and inflamed. If, at the end of the combustion, the gunpowder took fire, the spirit was said to be *above* or *over proof*. But if the spirit contained much water, the powder was rendered so moist that it did not take fire: in which case the spirit was said to be *under* or *below proof*.

Rectified spirit contains from 54 to 64 per cent. of absolute alcohol; and its specific gravity is fixed by the London and Edinburgh Colleges of Physicians at 0·838, whilst the Dublin College fixes it at 0·840.

In commerce the strength of mixtures of alcohol and water are stated at so many

Digitized by Google

degrees, according to Sykes's hydrometer, above or below proof. This instrument will be explained under the head of ALCOHOLOMETRY.

As will have been understood by the preceding remarks, the specific gravity or density of mixtures of alcohol and water rises with the diminution of the quantity of alcohol present; or, in other words, with the amount of water. And since the strength of spirits is determined by ascertaining their density, it becomes highly important to determine the precise ratio of this increase. This increase in density with the amount of water, or diminution with the quantity of alcohol, is, however, not directly proportional, in consequence of the contraction of volume which mixtures of alcohol and water suffer.

It therefore became necessary to determine the density of mixtures of known composition, prepared artificially. This has been done recently with great care by Mr. Drinkwater*; and the following Table by him is recommended as one of the most accurate.

Table of the Quantity of Alcohol, BY WEIGHT, *contained in Mixtures of Alcohol and Water of the following Specific Gravities:—*

Specific Gravity at 60° F.	Alcohol per cent. by weight.	Specific Gravity at 60° F.	Alcohol per cent. by weight.	Specific Gravity at 60° F.	Alcohol per cent. by weight.	Specific Gravity at 60° F.	Alcohol per cent. by weight.	Specific Gravity at 60° F.	Alcohol per cent. by weight.

·9968	1·73	·9935	3·61	·9902	5·64				

The preceding Table, though very accurate so far as it goes, is not sufficiently extensive for practical purposes, only going, in fact, from 6 to 10 per cent. of alcohol; the Table of Tralle's (page 49) extends to 50 per cent. of absolute alcohol.

Moreover, Drinkwater's Table has the (practical) disadvantage (though scientifically more correct and useful) of stating the per-centage *by weight*; whereas in Tralle's Table it is given by *volume*. And since liquors are vended by measure, and not by weight, the centesimal amount by volume is usually preferred. But as the bulk of

* Memoirs of the Chemical Society, vol. iii. p. 454.

Digitized by Google

liquids generally, and particularly that of alcohol, is increased by heat, it is necessary that the statement of the density in a certain volume should have reference to some normal temperature. In the construction of Tralle's Table the temperature of the liquids was 60° F.; and of course, in using it, it is necessary that the density should be observed at that temperature.

In order to convert the statement of the composition *by volume* into the content by weight, it is only necessary to multiply the per-centage of alcohol by volume by the specific gravity of absolute alcohol, and then divide by the specific gravity of the liquid.

It has been thought desirable to retain the following remarks by Dr. Ure, and to give Mr. Gilpin's tables in addition to the others.

The importance of extreme accuracy in determining the density of alcoholic mixtures in the United Kingdom, on account of the great revenue derived from them to the State, and their consequent high price in commerce, induced the Lords of the Treasury a few years ago to request the Royal Society to examine the construction and mode of applying the instrument now in use for ascertaining and charging the duty on spirits. This instrument, which is known and described in the law as Sikes's hydrometer, possesses, in many respects, decided advantages over those formerly in use. The committee of the Royal Society state, that a definite mixture of alcohol and water is as invariable in its value as absolute alcohol can be; and can be more readily, and with equal accuracy, indentified by that only quality or condition to which recourse can be had in practice, namely, specific gravity. The committee further proposed, that the standard spirit be that which, consisting of alcohol and water alone, shall have a specific gravity of 0·92 at the temperature of 62° F., water being unity at the same temperature; or, in other words, that it shall at 62° weigh $\frac{92}{100}$ths or $\frac{12}{13}$ths of an equal bulk of water at the same temperature.

This standard is rather stronger than the old proof, which was $\frac{12}{13}$ths or 0·923; or in the proportion of nearly 1·1 gallon of the present proof spirit per cent. The proposed standard will contain nearly one-half by weight of absolute alcohol. The hydrometer ought to be so graduated as to give the indication of strength; not upon an arbitrary scale, but in terms of specific gravity at the temperature of 62°.

The committee recommend the construction of an equation table, which shall indicate the same strength of spirit at every temperature. Thus in standard spirit at 62° the hydrometer would indicate 920, which in this table would give proof spirit. If that same spirit were cooled to 40°, the hydrometer would indicate some higher number; but which, being combined in the table with the temperature as indicated by the thermometer, should still give proof or standard spirit as the result.

It is considered advisable, in this and the other tables, not to express the quality of the spirit by any number over or under proof, but to indicate at once the number of gallons of standard spirit contained in, or equivalent to, 100 gallons of the spirit under examination. Thus, instead of saying 23 over proof, it is proposed to insert 123; and in place of 35·4 under proof, to insert its difference to 100, or 64·6.

It has been considered expedient to recommend a second table to be constructed, so as to show the bulk of spirit of any strength at any temperature, relative to a standard bulk of 100 gallons at 62°. In this table, a spirit which had diminished in volume, at any given temperature, 0·7 per cent., for example, would be expressed by 99·3; and a spirit which had increased at any given temperature 0·7 per cent., by 100·7.

When a sample of spirit, therefore, has been examined by the hydrometer and thermometer, these tables will give first the proportion of standard spirit at the observed temperature, and next the change of bulk of such spirit from what it would be at the standard temperature. Thus, at the temperature of 51°, and with an indication (specific gravity) of 8240, 100 gallons of the spirit under examintion would be shown by the first table to be equal to 164·8 gallons of standard spirit of that temperature; and by the second table it would appear that 99·3 gallons of the same spirit would become 100 at 62°, or in reality contain the 164·8 gallons of spirit in that state only in which it is to be taxed.

But as it is considered that neither of these tables can alone be used for charging the duty (for neither can express the actual quantity of spirit of a specific gravity of 0·92 at 62° in 100 gallons of stronger or weaker spirit at temperatures above or below 62°), it is considered essential to have a third table, combining the two former, and expressing this relation directly, so that upon mere inspection it shall indicate the proportion of standard spirit in 100 gallons of that under examination in its then present state. In this table the quantities should be set down in the actual number of gallons of standard spirit at 62°, equivalent to 100 of the spirit under examination; and the column of quantities may be expressed by the term *value*, as it in reality expresses the proportion of the only valuable substance present.

9	113·4		6	113·4	
90	113·3		7	113·3	
3	113·1		9	113·1	

The mixture of alcohol and water, taken as spirit in Mr. Gilpin's tables, is that of which the specific gravity is 0·825 at 60° F., water being unity at the same temperature. The specific gravity of water at 60° being 1000, at 62° it is 99,981. Hence, in order to compare the specific gravities given by Mr. Gilpin with those which would result when the specific gravity of water at 62° is taken at unity, all the former numbers must be divided by 99,981.

Table of the Specific Gravities of different Mixtures, BY WEIGHT, *of Alcohol and Water, at different Temperatures; constructed by Mr. Gilpin, for the use of the British Revenue on Spirits.*

Temperature, Fahr.	Pure Alcohol.	100 Alcohol 5 Water.	100 Alcohol 10 Water.	100 Alcohol 15 Water.	100 Alcohol 20 Water.	100 Alcohol 25 Water.	100 Alcohol 30 Water.	100 Alcohol 35 Water.	100 Alcohol 40 Water.	100 Alcohol 45 Water.	100 Alcohol 50 Water.

Experiments were made, by direction of the committee, to verify Gilpin's tables, which showed that the error introduced in ascertaining the strength of spirits by tables founded on Gilpin's numbers must be quite insensible in the practice of the Revenue. The discrepancies thus detected, on a mixture of a given strength, did not amount in any one instance to unity in the fourth place of decimals. From a careful inspection of such documents the committee are of opinion that Gilpin's tables possess a degree of accuracy far surpassing what could be expected, and sufficiently perfect for all practical or scientific purposes.

The following Table is given by Mr. Lubbock, for converting the *apparent* specific gravity, or *indication*, into true specific gravity :—

Indication.	— Temperature.								+				Indication.

In order, however, to employ this Table for ascertaining the strength of mixtures of alcohol and water of different densities (which is the practical use of such Tables), it is absolutely necessary that the determination of the density should be performed at an invariable temperature,—viz. 60° F. The methods of determining the density will be hereafter described; but it is obvious that practically the experiment cannot be conveniently made at any fixed temperature, but must be performed at that of the atmosphere.

M. Gay-Lussac has constructed a most valuable Table, of which the following is an abstract, which is supplied with his "Alcoomètre." (See ALCOHOLOMETRY.) It enables one to ascertain, from the observed density at any given temperature, the density at the normal temperature 15·5° C. (60° F.), and hence the strength; or, *vice versâ*, from the observed density at 60° F. to find the density at any other temperature.

The first vertical column of this Table contains the temperatures, from 0° to 30° C.; and the first horizontal line the indications of the alcoomètre. In the same Table he has most ingeniously inserted a correction of the volume of the spirits when the temperature differs from 15·5° C. (60° F.). All the numbers printed in small characters, under each *real strength*, i.e. per-centage of absolute alcohol, indicate the volume which 1000 *litres* (*the litre being* 1·760773 *pints*) of a spirituous liquor would have when measured at the temperature at which its apparent strength is given.

The *boiling point* of mixtures of alcohol and water likewise differs with the strength of such mixtures.

According to Gay-Lussac, absolute alcohol boils at 78·4° C. (173° F.) under a pressure of 760 *millimetres* (*the millimetre being* 0·03937 *English inches*). When mixed with water, of course its boiling point rises in proportion to the quantity of water present, as is the case in general with mixtures of two fluids of greater and less volatility. A mixture of alcohol and water, however, presents this anomaly, according to Soëmmering: when the mixture contains less than six per cent. of alcohol, those portions which first pass off are saturated with water, and the alcoholic solution in the retort becomes richer, till absolute alcohol passes over; but when the mixture contains more than six per cent. of water the boiling point rises, and the quantity of alcohol in the distillate steadily diminishes as the distillation proceeds.

According to Gröning's researches, the following temperatures of the alcoholic vapours correspond to the accompanying contents of alcohol in per-centage of volume which are disengaged in the boiling of the spirituous liquid.

Temperature.	Alcoholic content of the vapour.	Alcoholic content of the boiling liquid.	Temperature.	Alcoholic content of the vapour.	Alcoholic content of the boiling liquid.

Gröning undertook this investigation in order to employ the thermometer as an alcoholometer in the distillation of spirits; for which purpose he thrust the bulb of the thermometer through a cork inserted into a tube fixed in the capital of the still. The state of the barometer ought also to be considered in making comparative experiments of this kind. Since, by this method, the alcoholic content may be compared with the temperature of the vapour that passes over at any time, so, also, the contents of the whole distillation may be found approximately; and the method serves as a convenient means of making continual observations on the progress of the distillation.

From the mean of a great many experiments, Dr. Ure drew up the following Table, which shows the boiling point of alcohol of various specific gravities:—

Boiling Point.	Specific Gravity.	Boiling Point.	Specific Gravity.
178·5 F.	0·9200	185·6 F.	0·9665
179·75 „	0·9321	189·0 „	0·9729
180·4 „	0·9420	191·8 „	0·9786
182·01 „	0·9516	196·4 „	0·9850
183·40 „	0·960	202·0 „	0·992

Density of the Vapour.—One volume of alcohol yields 488·3 volumes of vapour at 212° F. The specific gravity of the vapour, taking air as unity, was found by Gay-Lussac to be 1·6133. [Its vapour-density, referred to hydrogen as unity, is 13·3605?]

Spirituous vapour passed through an ignited tube of glass or porcelain is converted into carbonic oxide, water, hydrogen, carburetted hydrogen, olefiant gas, naphthaline, empyreumatic oil, and carbon; according to the degree of heat and nature of the tube, these products vary. Anhydrous alcohol is a non-conductor of electricity, but is decomposed by a powerful voltaic battery. Alcohol burns in the air with a blue flame into carbonic acid and water; the water being heavier than the spirit, because 46 parts of alcohol contain 6 of hydrogen, which form 54 of water. In oxygen the combustion is accompanied with great heat, and this flame, directed through a small tube, powerfully ignites bodies exposed to it.

Platinum in a finely divided state has the property of determining the combination of alcohol with the oxygen of the air in a remarkable manner. A ball of spongy platinum, placed slightly above the wick of a lamp fed by spirit and communicating with the wick by a platinum wire, when once heated, keeps at a red heat, gradually burning the spirit. This has been applied in the construction of the so-called "philosophical pastilles;" eau-de-cologne or other perfumed spirit being thus made to diffuse itself in a room.

Mr. Gill has also practically applied this in the construction of an alcohol lamp without flame.

A coil of platinum wire, of about the one-hundredth part of an inch in thickness, is coiled partly round the cotton wick of a spirit lamp, and partly above it, and the lamp lighted to heat the wire to redness; on the flame being extinguished, the alcohol vapour keeps the wire red hot for any length of time, so as to be in constant readiness to ignite a match, for example. This lamp affords sufficient light to show the hour by a watch in the night, with a very small consumption of spirit.

This property of condensing oxygen, and thus causing the union of it with combustible bodies, is not confined to platinum, but is possessed, though in a less degree, by other porous bodies. If we moisten sand in a capsule with absolute alcohol, and cover it with previously heated nickel powder, protoxide of nickel, cobalt powder, protoxide of cobalt, protoxide of uranium, or oxide of tin (these six bodies being procured by ignition of their oxalates in a crucible), or finely powdered peroxide of manganese, combustion takes place, and continues so long as the spirituous vapour lasts.

Solvent Power.—One of the properties of alcohol most valuable in the arts is its *solvent power.*

It dissolves gases to a very considerable extent, which gases, if they do not enter into combinations with the alcohol, or act chemically upon it, are expelled again on boiling the alcohol.

Several salts, especially the deliquescent, are dissolved by it, and some of them give a colour to its flame; thus the solutions of the salts of strontia in alcohol burn with a *crimson flame*, those of copper and borax with a *green* one, lime a *reddish*, and baryta with a *yellow* flame.

This solvent power is, however, most remarkable in its action upon resins, ethers essential oils, fatty bodies, alkaloids, as well as many organic acids. In a similar

Digitized by Google

way it dissolves iodine, bromine, and in small quantities sulphur and phosphorus. In general it may be said to be an excellent solvent for most hydrogenised organic substances.

In consequence of this property it is most extensively used in the chemical arts: *e.g.* for the solution of gum-resins, &c., in the manufacture of varnishes; in pharmacy, for the separating of the active principles of plants, in the preparation of tinctures. It is also employed in the formation of chloroform, ether, spirits of nitre, &c.

ALCOHOL, METHYLATED. It was for a long time a great desideratum for the manufacturer to obtain spirit free from duty. The Government, feeling the necessity for this, have sanctioned the sale of spirit which has been flavoured with methyl-alcohol, so as to render it unpalatable, *free of duty*, under the name of "*methylated spirit.*" This methylated spirit can now be obtained, in large quantities only, and by giving suitable security to the Board of Inland Revenue of its employment for manufacturing purposes only, and must prove of great value to those manufacturers who are large consumers.

Professors Graham, Hofmann, and Redwood, in their "Report on the Supply of Spirit of Wine, free of duty, for use in the Arts and Manufactures," addressed to the Chairman of the Board of Inland Revenue, came to the following conclusions:—

"From the results of this inquiry it has appeared that means exist by which spirit of wine, produced in the usual way, may be rendered unfit for human consumption, as a beverage, without materially impairing it for the greater number of the more valuable purposes in the arts to which spirit is usually applied. To spirit of wine, of not less strength than corresponds to density 0·830, it is proposed to make an addition of 10 per cent. of purified wood naphtha (*wood or methylic spirit*), and to issue this mixed spirit for consumption, duty free, under the name of *Methylated Spirit.* It has been shown that methylated spirit resists any process for its purification; the removal of the substance added to the spirit of wine being not only difficult, but, to all appearance, impossible; and further, that no danger is to be apprehended of the methylated spirit being ever compounded so as to make it palatable. . . . . It may be found safe to reduce eventually the proportion of the mixing ingredient to 5 per cent., or even a smaller proportion, although it has been recommended to begin with the larger proportion of 10 per cent."

And further, the authors justly remark:—"The command of alcohol at a low price is sure to suggest a multitude of improved processes, and of novel applications, which can scarcely be anticipated at the present moment. It will be felt far beyond the limited range of the trades now more immediately concerned in the consumption of spirits; like the repeal of the duty on salt, it will at once most vitally affect the chemical arts, and cannot fail, ultimately, to exert a beneficial influence upon many branches of industry."

And in additional observations, added subsequently to their original Report, the chemists above named recommend the following restriction upon the sale of the methylated spirit:—"That the methylated spirit should be issued, by agents duly authorised by the Board of Inland Revenue, to none but manufacturers, who should themselves consume it; and that application should always be made for it according to a recognised form, in which, besides the quantity wanted, the applicant should state the use to which it is to be applied, and undertake that it should be applied for that purpose only. The manufacturer might be permitted to retail varnishes and other products containing the methylated spirit, but not the methylated spirit itself in an unaltered state." They recommend that the methylated spirit should not be made with the ordinary crude, very impure wood naphtha, since this could not be advantageously used as a solvent for resins by hatters and varnish makers, as the less volatile parts of the naphtha would be retained by the resins after the spirit had evaporated, and the quality of the resin would be thus impaired. If, however, the methylated spirit be originally prepared with the crude wood naphtha, it may be purified by a simple distillation from 10 per cent. of potash.

It appears that the boon thus afforded to the manufacturing community of obtaining spirit *duty free* has been acknowledged and appreciated; and now for most purposes, where the small quantity of wood-spirit does not interfere, the methylated spirit is generally used.

It appears that even ether and chloroform, which one would expect to derive an unpleasant flavour from the wood spirit, are now made of a quality quite unobjectionable from the methylated spirit; but care should be taken, especially in the preparation of medicinal compounds, not to extend the employment of the methylated spirit beyond its justifiable limits, lest so useful an article should get into disrepute.* Methylated spirit can be procured also in small quantities from the wholesale dealers, containing in solution 1oz. to the gallon of shellac. under the name of "finish."

* Some difference of opinion appears to exist whether *Chloroform* can be obtained *pure* from methylated spirit. See METHYL.

ALCOHOLATES. Graham has shown that alcohol forms crystallisable compounds with several salts. These bodies, which he calls "*Alcoholates*," are in general rather unstable combinations, and almost always decomposed by water. Among the best known are the following:—

Alcoholate of chloride of calcium - - -	$2\ C^4H^6O^2$, Ca Cl
„ „ of zinc - - -	$C^4H^6O^2$, Zn Cl
„ bichloride of tin - - -	$C^4H^6O^2$, Tn Cl
„ nitrate of magnesia - - -	$3\ C^4H^6O^2$, Mg O, NO_5

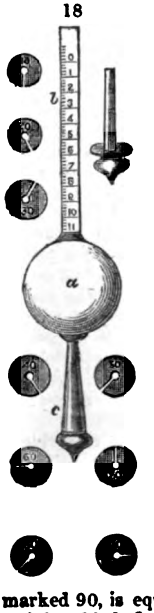
ALCOHOLOMETRY, or ALCOÖMETRY. *Determination of the Strength of Mixtures of Alcohol and Water.* Since the commercial value of the alcoholic liquors, commonly called "spirits," is determined by the amount of pure or absolute alcohol present in them, it is evident that a ready and accurate means of determining this point is of the highest importance to all persons engaged in trade in such articles.

If the mixture contain nothing but alcohol and water, it is only necessary to determine the *density* or *specific gravity* of such a mixture; if, however, it contain saccharine matters, colouring principles, &c., as is the case with wine, beer, &c., other processes become necessary, which will be fully discussed hereafter.

The determination of the specific gravity of spirit, as of most other liquids, may be effected, with perhaps greater accuracy than by any other process, by means of a stoppered specific-gravity bottle. If the bottle be of such a size as exactly to hold 1000 grains of distilled water at 60° F., it is only necessary to weigh it full of the spirit at the same temperature, when (the weight of the bottle being known) the specific gravity is obtained by a very simple calculation. See SPECIFIC GRAVITY.

This process, though very accurate, is somewhat troublesome, especially to persons unaccustomed to accurate chemical experiments, and it involves the possession of a delicate balance. The necessity for this is however obviated by the employment of one of the many modifications of the common *hydrometer*. This is a floating instrument, the use of which depends upon the principle, that a solid body immersed into a fluid is buoyed upwards with a force equal to the weight of the fluid which it displaces, *i.e.* to its own bulk of the fluid; consequently, the denser the spirituous mixture, or the less alcohol it contains, the higher will the instrument stand in the liquid; and the less dense, or the more spirit it contains, the lower will the apparatus sink into it.

There are two classes of hydrometers. 1st. Those which are always immersed in the fluid to the same depth, and to which weights are added to adjust the instrument to the density of any particular fluid. Of this kind are Fahrenheit's, Nicholson's, and Guyton de Morveau's hydrometers.



2nd. Those which are always used with the same weight, but which sink into the liquids to be tried, to different depths, according to the density of the fluid. Of this class are most of the common glass hydrometers, such as Beaumé's, Curteis's, Gay-Lussac's, Twaddle's, &c.

Sykes's and Dicas's combine both principles. See HYDROMETERS.

Sykes's hydrometer, or alcoholometer, is the one employed by the Board of Excise, and therefore the one most extensively used in this country.

This instrument does not immediately indicate the density or the per-centage of absolute alcohol, *but the degree above or below proof*—the meaning of which has been before detailed. (p. 44.)

It consists of a spherical ball or float, *a*, with an upper and lower stem of brass, *b* and *c*. The upper stem is graduated into ten principal divisions, which are each subdivided into five parts. The lower stem, *c*, is made conical, and has a loaded bulb at its extremity. There are nine movable weights, numbered respectively by tens from 10 to 90. Each of these circular weights has a slit in it, so that it can be placed on the conical stem, *c*. The instrument is adjusted so that it floats with the surface of the fluid coincident with zero on the scale, in a spirit of specific gravity ·825 at 60° F., this being accounted by the Excise as "*standard alcohol*." In weaker spirit, which has therefore a greater density, the hydrometer will not sink so low; and if the density be much greater, it will be necessary to add one of the weights to cause the entire immersion of the bulb of the instrument. Each weight represents so many principal divisions of the stem, as its number indicates; thus, the heaviest weight, marked 90, is equivalent to 90 divisions of the stem, and the instrument, with the weight added, floats at 0 in distilled water. As each principal division on the stem is

Digitized by Google

divided into five subdivisions, the instrument has a range of 500 degrees between the standard alcohol (specific gravity ·825) and water. There is a line on one of the side faces of the stem, *b*, near division 1 of the drawing, at which line the instrument with the weight 60 attached to it floats in spirit exactly of the strength of *proof*, at a temperature of 51° F.

In using this instrument, it is immersed in the spirit, and pressed down by the hand until the whole of the graduated portion of the upper stem is wet. The force of the hand required to sink it will be a guide to the selection of the proper weight. Having taken one of the circular weights necessary for the purpose, it is slipped on to the lower conical stem. The instrument is again immersed, and pressed down as before to 0, and then allowed to rise and settle at any point. The eye is then brought to the level of the surface of the spirit, and the part of the stem cut by the surface, *as seen from below*, is marked. The number thus indicated by the stem is added to the number of the weight, and the sum of these, together with the *temperature* of the spirit, observed at the same time by means of a thermometer, enables the operator, by reference to a Table which is sold to accompany the instrument, to find the strength of the spirit tested.

These Tables are far too voluminous to be quoted here; and this is unnecessary, since the instrument is never sold without them.

A modification of Sykes's hydrometer has been recently adopted for testing alcoholic liquors which is perhaps more convenient, as the necessity for the loading weights is done away with, the stem being sufficiently long not to require them. It is constructed of glass, and is in the shape of a common hydrometer, the stem being divided into degrees; it carries a small spirit thermometer in the bulb, to which a scale is fixed, ranging from 30° to 82° F. (0 to 12° C.) There are Tables supplied with the hydrometer, which are headed by the degrees and half degrees of the thermometric scale; and the corresponding content of spirit, over or under proof at the respective degree of the Table, is placed opposite each degree of the hydrometer.

By means of either of these instruments, and by the use of the Tables accompanying them, we learn the strength, in degrees, *above or below proof*; and the following Table by Dr. Ure will be found most useful in converting these numbers into specific gravities.

Per cent. over Proof.	Specific Gravity.	Per cent. over Proof.	Specific Gravity.	Per cent. over Proof.	Specific Gravity.	Per cent. over Proof.	Specific Gravity.	Per cent. over Proof.	Specific Gravity.

And now, by reference either to Drinkwater's, Tralle's, or Gay-Lussac's Tables, the operator will be enabled to find, by the knowledge of the density or specific gravity, at the temperature at which the operation was performed, the per-centage of real alcohol, either by weight or by volume.

In France, Gay-Lussac's *alcoolomètre* is usually employed. It is a common glass hydrometer, with the scale on the stem divided into 100 parts or degrees. The lowest division, marked 0, denotes the specific gravity of pure water; and 100, that of absolute alcohol, both at 15° C. (59° F.) The intermediate degrees, of course, show the per-centage of absolute alcohol by volume at 15° C.; and the instrument is accompanied by the Tables already given for ascertaining the per-centage at any other temperature.

Alcoholometry of Liquids containing besides Alcohol, Saccharine Matters, Colouring Principles, &c., such as Wines, Beer, Liqueurs, &c.

In order to determine the proportion of absolute alcohol contained in wines, or other mixtures of alcohol and water with saccharine and other non-volatile substances, the most accurate method consists in submitting a known volume of the liquid to distillation (in a glass retort, for instance); then, by determining the specific gravity of the distilled product, to ascertain the per-centage of alcohol in this distillate, which may be regarded as essentially a mixture of pure alcohol and water. The distillation is carried on until the last portions have the gravity of distilled water; by then ascertaining the total volume of the distillate, and with the knowledge of its per-centage of alcohol and the volume of the original liquor used, the method of calculating the quantity of alcohol present in the wine, or other liquor, is sufficiently obvious.

In carrying out these distillations care must be taken to prevent the evaporation of the spirit from the distillate, by keeping the condenser cool. And Professor Mulder recommends the use of a refrigerator, consisting of a glass tube fixed in the centre of a jar, so that it may be kept filled with cold water. The tube must be bent at a right angle, and terminate in a cylindrical graduated measure-glass, shaped like a bottle.*

It is well to continue the distillation until about two-thirds of the liquid has passed over.

This process, though the most accurate for the estimation of the strength of alcoholic liquors, is still liable to error. The volatile acids and ethers pass over with the alcohol into the distillate, and, to a slight extent, affect the specific gravity. This error may be, to a great extent, overcome by mixing a little chalk with the wine, or other liquor, previous to distillation.

By this method Professor Brande made, some years ago, determinations of the strength of the following wines, and other liquors†:—

M. l'Abbé Brossard-Vidal, of Toulon*, has proposed to estimate the strength of alcoholic liquors by determining their boiling point. Since water boils at 100° C. (212° F.), and absolute alcohol at 78·4° (173° F.), it is evident that a mixture of water and alcohol will have a higher boiling point the larger the quantity of water present in it. This method is even applicable to mixtures containing other bodies in solution besides spirit and water, since it has been shown that sugar and salts, when present (in moderate quantities), have only a very trifling effect in raising the boiling point; and the process has the great advantage of facility and rapidity of execution, though of course not comparable to the method by distillation, for accuracy.

Mr. Field's patent (1847) alcoholometer is likewise founded upon the same principle. The instrument was subsequently improved by Dr. Ure.

The apparatus consists simply of a spirit-lamp placed under a little boiler containing the alcoholic liquor, into which fits a thermometer of very fine bore.

When the liquor is stronger than proof spirit, the variation in the boiling point is so small that an accurate result cannot possibly be obtained; and, in fact, spirit approaching this strength should be diluted with an equal volume of water before submitting it to ebullition, and then the result doubled.

Another source of error is the elevation of the boiling point, when the liquor is kept heated for any length of time; it is, however, nearly obviated by the addition of common salt to the solution in the boiler of the apparatus, in the proportion of 35 or 40 grains. In order to correct the difference arising from higher or lower pressure of the atmosphere, the scale on which the thermometric and other divisions are marked is made movable up and down the thermometer tube; and every time, before commencing a set of experiments, a preliminary experiment is made of boiling some pure distilled water in the apparatus, and the zero point on the scale (which indicates the boiling point of water) is adjusted at the level of the surface of the mercury. On p. 54 will be found a Table showing the boiling point of alcohol of different specific gravities.

But even when performed with the utmost care, this process is still liable to very

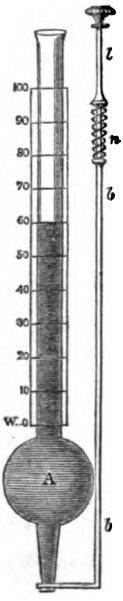
* Comptes Rendus, xxvii. 374.

Digitized by Google

considerable errors, for it is extremely difficult to observe the boiling point to within a degree ; and after all, the fixed ingredients present undoubtedly do seriously raise the boiling point of the mixture—in fact, to the extent of from half to a whole degree, according to the amount present.

Silbermann's Method.—M. Silbermann* has proposed another method of estimating the strength of alcoholic liquors, based upon their expansion by heat. It is well known that, between zero and 100° C. (212° F.), the dilatation of alcohol is triple that of water, and this difference of expansion is even greater between 25° C. (77° F.) and 50° C. (122° F.); it is evident, therefore, that the expansion between these two temperatures becomes a measure of the amount of alcohol present in any mixture. The presence of salts and organic substances, such as sugar, colouring, and extractive matters, in solution or suspension in the liquid, is said not materially to affect the accuracy of the result; and M. Silbermann has devised an apparatus for applying this principle, in a ready and expeditious manner, to the estimation of the strength of alcoholic liquors. The instrument may be obtained of the philosophical instrument makers of London and of Liverpool.

19

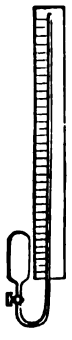


It consists of a brass plate, on which are fixed—1st. An ordinary mercurial thermometer graduated from 22° to 50° C. (77° to 122° F.), these being the working temperatures of the *dilatatometer*; and 2ndly, the dilatatometer itself, which consists of a glass pipette, open at both ends, and of the shape shown in the figure. A valve of cork or india-rubber closes the tapering end A, which valve is attached to a rod, *b b*, fastened to the supporting plate, and connected with a spring, *n*, by which the lower orifice of the pipette can be opened or closed at will. The pipette is filled, exactly up to the zero point, with the mixture to be examined—this being accomplished by the aid of a piston working tightly in the long and wide limb of the pipette; the action of which serves also another valuable purpose—viz., that of drawing any bubbles of air out of the liquid. By now observing the dilatation of the column of liquid when the temperature of the whole apparatus is raised, by immersion in a water-bath, from 25° to 50°, the co-efficient of expansion of the liquid is obtained, and hence the proportion of alcohol—the instrument being, in fact, so graduated, by experiments previously made upon mixtures of known composition, as to give at once the per-centage of alcohol.

Another alcoholometer, which, like the former, is more remarkable for the great facility and expedition with which approximative results can be obtained than for a high degree of accuracy, was invented by M. Geisler, of Bonn, and depends upon the measurement of the tension of the vapour of the liquid, as indicated by the height to which it raises a column of mercury.

Geisler's Alcoholometer.—It consists of a closed vessel in which the alcoholic mixture is raised to the boiling point, and the tension of the vapour observed by the depression of a column of mercury in one limb of a tube, the indication being rendered more manifest by the elevation of the other end of the column.

20



The wine or other liquor of which it is desired to ascertain the strength, is put into the little flask, F, which, when completely filled, is screwed on to the glass which contains mercury, and is closed by a stopcock at S. The entire apparatus, which at present is an inverted position, is now stood erect, the flask and lower extremity of the tube being immersed in a water-bath. The vinous liquid is thus heated to the boiling point, and its vapour forces the mercury up into the long limb of the tube. The instrument having been graduated, once for all, by actual experiment, the per-centage of alcohol is read off at once on the stem by the height to which the mercurial column rises.

To show how nearly the results obtained by this instrument agree with those obtained by the distillation process, comparative experiments were made on the same wines by Dr. Bence Jones.†

Tabarié's Method.—There is another method of determining the alcoholic contents of mixtures, which especially recommends itself on account of its simplicity. The specific gravity of the liquor is first determined, half its volume is next evaporated in the open air, sufficient water is then added to the remainder to restore its original volume, and the specific gravity again ascertained. By deducting the specific gravity before the expulsion of the alcohol from that obtained afterwards, the difference gives a specific gravity indicating the per-centage of alcohol, which may be found by referring to Gay-Lussac's or one of the other Tables. Tabarié has constructed a peculiar instrument for determining these specific gravities, which he calls an œnometer; but they may be performed either by a specific-gravity bottle or by a hydrometer in the usual way.

Of course this method cannot be absolutely accurate; nevertheless, Prof. Mulder's experience with it has led him to prefer it to any of the methods before described, especially where a large number of samples have to be examined. He states that the results are almost as accurate as those obtained by distillation. The evaporation of the solution may be accelerated by conducting hot steam through it.

Adulterations.— Absolute alcohol should be entirely free from water. This may be recognised by digesting the spirit with pure anhydrous sulphate of copper. If the spirit contain any water, the white salt becomes tinged blue, from the formation of the blue hydrated sulphate of copper.

Rectified spirit, proof spirit, and the other mixtures of pure alcohol and water, should be colourless, free from odour and taste. If containing methylic or amylic alcohols, they are immediately recognised by one or other of these simple tests.

Dr. Ure states that if wood spirit be contained in alcohol, it may be detected to the greatest minuteness by the test of caustic potash, a little of which, in powder, causing wood spirit to become speedily yellow and brown, while it gives no tint to alcohol. Thus 1 per cent. of wood spirit may be discovered in any sample of spirits of wine.

The admixture with a larger proportion than the due amount of water is of course determined by estimating the per-centage of absolute alcohol by one or other of the several methods just described in detail.

The adulterations and sophistications to which the various spirits known as rum, brandy, whisky, gin, &c., are subjected, will be best described under these respective heads, since these liquors are themselves mixtures of alcohol and water with sugar, colouring matters, flavouring ethers, &c.

Uses.—The great use of alcohol, in its various states of mixture, is, and has been from time immemorial, as a *beverage*. There cannot be a doubt that alcoholic liquors

Digitized by Google

are beneficial to most healthy persons, when *moderately* enjoyed; and the man who advocates their rational *use* cannot be held answerable for their *abuse*.

Absolute alcohol (or strong spirits) acts locally as an irritant, contracting the tissues; but its effects on the organism, when taken internally, arises from its action, by the nerves, on the brain. Dr. Pereira has graphically described three stages of their effects:—

1. First or mildest degree - Excitement.
2. Second degree - - - Intoxication, or drunkenness.
3. Third degree - - - Coma, or true apoplexy.

These effects are tolerably familiar, and for a more minute description of them we must refer to Dr. Pereira* and other medical authors.

The important applications of alcohol in the arts, as a solvent for resins, &c., have been before alluded to. To the chemist it is a most valuable agent of separation. By its means he is enabled, in complicated organic mixtures, to separate those substances which are soluble from those which are insoluble in this menstruum. It may likewise be employed for separating certain salts—*e.g.* the chloride of strontium from that of barium, &c. &c.

From it are also manufactured ether, chloroform, and, indirectly, acetic acid; and in pharmacy, sweet spirits of nitre, the various tinctures, &c. &c.

* Geneva not separated in the Statistical Abstract for the United Kingdom after 1856.

Digitized by Google

These numbers show the alterations which are taking place in the spirit-trading and spirit-drinking tendencies of the people of this country. In 1854 (see Tables in last edition) the value of the spirits imported was 2,791,047*l.*; while in 1863 it had fallen to 1,828,604*l.*, and in 1864 it was 2,275,049*l.* At the same time we find that the value of the wine imported in 1854 was 3,616,369*l.*; while in 1863 it was 4,497,343*l.*, and in 1864 5,002,884*l.* From this we may infer that a real improvement is taking place in the social condition of the people. It must not be forgotten that this statement does not include beer, which is the staple beverage of a very large portion of the community; and the increase in the consumption of malt liquors is only keeping pace with the increase of population.

The following are the quantities of spirits charged with duties of excise in each of the years named:—

	Gallons.		Gallons.		Gallons.
1842 -	18,841,890	1850 -	23,919,432	1858 -	23,686,751
1844 -	20,608,525	1852 -	25,270,262	1860 -	21,873,369
1846 -	24,106,697	1854 -	26,148,511	1862 -	19,700,250
1848 -	22,234,379	1856 -	23,922,453	1864 -	21,039,582

Every English distiller has now to pay a licence-duty of ten guineas before he can lawfully conduct operations, and afterwards a duty of 7*s.* 10*d.* per imperial gallon of spirits, proof strength, which he produces.

The Scotch and Irish distillers had to pay the same licence-fee as the English; and in addition to this, the Scotch distiller paid a duty of 4*s.* 8*d.* per imperial gallon of proof strength, and the Irish a duty of 3*s.* 4*d.*; but the duties are now equalised.

ALCOHOL RADICALS. The organic radicals containing hydrogen and carbon, which, when they replace half the hydrogen in a molecule of water, form alcohols. Ethyl and methyl are the best known. See METHYLATED SPIRIT.

ALDEHYDE. By this word is understood the fluid obtained from alcohol by the removal of two equivalents of hydrogen. Thus, alcohol being represented by the formula $C^4 H^6 O^2$, aldehyde becomes $C^4 H^4 O^2$. See LAMPIC ACID.

Preparation.—Aldehyde is prepared by various processes of oxidation. Liebig has published several methods, of which the following is perhaps the best. Three parts of peroxide of manganese, three of sulphuric acid, two of water, and two of alcohol of 80 per cent., are well mixed and carefully distilled in a spacious retort. The extreme volatility of aldehyde renders good condensation absolutely necessary. The contents of the retort are to be distilled over a gentle and manageable fire until frothing commences, or the distillate becomes acid. This generally takes place when about one-third has passed over. The fluid in the receiver is to have about its own weight of chloride of calcium added, and, after slight digestion, is to be carefully distilled on the water-bath. The distillate is again to be treated in the same way. By these processes a fluid will be obtained entirely free from water, but containing several impurities. To obtain the aldehyde in a state of purity it is, necessary, in the first place, to obtain aldehyde-ammonia; this may be accomplished in the the following manner:—The last distillate is to be mixed in a flask with twice its volume of ether, and, the flask being placed in a vessel surrounded by a freezing mixture, dry ammoniacal gas is passed in until the fluid is saturated. In a short time crystals of the compound sought separate in considerable quantity. The aldehyde-ammonia, being collected on a filter, or in the neck of a funnel, is to be washed with ether, and dried by pressure between folds of filtering paper, followed by exposure to the air. It now becomes necessary to obtain the pure aldehyde from the compound with ammonia. For this purpose two parts are to be dissolved in an equal quantity of water, and three parts of sulphuric acid, mixed with four of water, are to be added. The whole is to be distilled on the water-bath, the temperature, at first, being very low, and the operation being stopped as soon as the water boils. The distillate is to be placed in a retort connected with a good condensing apparatus, and, as soon as all the joints are known to be tight, chloride of calcium, in fragments, is to be added. The heat arising from the hydration of the chloride causes the distillation to commence, but it is carried on by a water-bath. The distillate, after one more rectification over chloride of calcium, at a temperature not exceeding 80° F., will consist of pure aldehyde. Aldehyde is a colourless, very volatile, and mobile fluid, having the density 0·800 at 32°. It boils, under ordinary atmospheric pressure, at 70° F. Its vapour density is 1·532. Its formula corresponds to four volumes of vapour; we consequently obtain the theoretical vapour density by multiplying its atomic weight = 44 by half the density of hydrogen, or ·0346. The number thus found is 1·5224, corresponding as nearly as could be desired to the experimental result.

Aldehyde is produced in a great number of processes, particularly during the destructive distillation of various organic matters, and in processes of oxidation. From

Digitized by Google

alcohol aldehyde may be procured by oxidation with platinum black, nitric acid, chromic acid, chlorine (in presence of water), or, as we have seen, a mixture of peroxide of manganese and sulphuric acid. Certain oils, by destructive distillation, yield it. Wood vinegar in the crude state contains aldehyde as well as wood spirit. Lactic acid, when in a combination with weak bases, yields it on destructive distillation. Various animal and vegetable products afford aldehyde by distillation with oxydising agents, such as sulphuric acid and peroxide of manganese, or bichromate of potash.

The word aldehyde, like that of alcohol, is gradually becoming used in a much more extended sense than it was formerly. By the term is now understood any organic substance which, by assimilating two equivalents of hydrogen, yields a substance having the properties of an alcohol, or, by taking up two equivalents of oxygen, yields an acid. It is this latter property which has induced certain chemists to say that there is the same relation between an aldehyde and its acid as between inorganic acids ending in *ous* and *ic*. Several very interesting and important substances are now known to belong to the class of aldehydes. The essential oils are, in several instances, composed principally of bodies having the properties of aldehydes. Among the most prominent may be mentioned the oils of bitter almonds, cumin, cinnamon, rue, &c. An exceedingly important character of the aldehydes is their strong tendency to combine with the bisulphites of ammonia, potash, and soda. By availing ourselves of this property, it becomes easy to separate bodies of this class from complex mixtures, and, consequently, enable a proximate analysis to be made. Now that the character of the aldehydes is becoming better understood, the chances of artficially producing the essential oils above alluded to in the commercial scale become greatly increased. Several have already been formed, and, although in very small quantities, the success has been sufficient to warrant sanguine hopes of success. A substitute for one of them has been for some years known under the very incorrect name of artificial oil of bitter almonds. See NITROBENZOLE. — C. G. W

ALANINE. (C^6 H^7 NO^4.) A peculiar substance, produced when aldehyde-ammonia is acted on by hydrocyanic and hydrochloric acids.

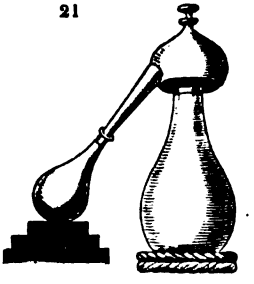
ALCIDÆ. A family of sea-birds, to which the Guillemots and Penguins belong. The Patagonian Penguin is larger than a goose, slate-coloured on the back, and white with a black mark on the breast, encircled by a citron-yellow cravat. The plumage is very close, and the breast is used as tippets and for trimming ladies' dresses.

ALDER. (*Aune*, Fr.; *Erle*, Germ.; *Alnus glutinosa*, Lin.) A tree, different species of which are indigenous to Europe, Asia, and America. The common alder seldom grows to a height of more than 40 feet. The wood is stated to be very durable under water. The piles at Venice, and those of Old London Bridge, are stated to have been of alder; and it was much used for pipes, pumps, and sluices. The charcoal of this wood is used for gunpowder.

ALE. The fermented infusion of pale malted barley, combined with infusion of hops. See BEER.

ALEMBIC, a Still. See DISTILLATION. The term is, however, applied to a still of peculiar construction, in which the *head*, or *capital*, is a separate piece, fitted and ground to the neck of the boiler, or cucurbit, or otherwise carefully united with a lute. The alembic has this advantage over the common retort, that the residue of distillation may be easily cleared out of the body. It is likewise capable, when skilfully managed, of distilling a much larger quantity of liquor in a given time than a retort of equal capacity. In France the term alembic, or rather *alambic*, is used to designate a glass still.

21



ALEMBROTH, SALT OF. The *salt of wisdom* of the alchemists; a compound of bichloride of mercury and sal ammoniac. If two atoms of bichloride of mercury are mixed with one atom of sal ammoniac and eight atoms of water, at 140° this mixture is fluid, but the salt of alembroth (*sal alembroth*) crystallises on cooling. It is composed of chloride of mercury and chloride of ammonium (NH^4ClH^8ClHO).

ALENÇON LACE. A French lace, of which it is one of the richest, finest, strongest, and most expensive. It has a six-sided mesh of two threads wove with pure hand-spun linen thread. See LACE.

ALGAROTH, POWDER OF. *Powder of Algarotti,—English Powder.* This salt was discovered by Algarotti, a physician of Verona. Chloride of antimony is formed by boiling black sulphide of antimony with hydrochloric acid: on pouring the solution into water, a white flocky precipitate falls, which is an oxychloride of antimony. If the water be hot, the precipitate is distinctly crystalline; this is the powder of algaroth. This oxychloride is used to furnish oxide of antimony in the preparation of tartar emetic.

ALGAROVILLA. This substance is called by the Spaniards *Algaroba*, from the resemblance it bears to the fruit of the Carob (*Ceratonia siliqua*), which is a native of Europe, in the southern countries of Spain and Portugal. It is the fruit of a tree which grows in Chili, of which the botanical name is *Prosopis pallida*, according to Captain Bagnald, R.N., who first brought a sample of it to this country in the year 1832. It consists of pods bruised and agglutinated more or less with the extractive exudation of the seeds and husks. According to a more recent determination, algarovilla is said to be the product of the tree Juga Marthæ of Santa Martha, a province of New Carthagena.

It is an astringent substance replete with tannin, capable, by its infusion in water, of tanning leather, for which purpose it possesses more than four times the power of good oak-bark. Its active matter is very soluble in water at a boiling temperature. The seeds are merely nutritive and demulcent, but contain no astringent property. This resides in the husks. The seeds in the entire pod constitute about one-fifth of the weight, and they are three or four in number in each oblong pod. Alcohol of 60 per cent. over proof dissolves 64 parts in 100 of this substance. The solution consists chiefly of tannin, with a very little resinous matter. Water dissolves somewhat more of it, and affords a very styptic-tasted solution, which precipitates solution of isinglass very copiously, like infusion of galls and catechu. Its solution forms with sulphate of iron a black precipitate.

ALGÆ. (*Varech*, Fr.; *Seegras*, or *Alge*, Germ.) A tribe of subaqueous plants, including the seaweeds (*fucus*) and the lavers (*ulva*) growing in salt water, and the fresh-water confervas. We have only to deal with those seaweeds which are of any commercial value. These belong to the great division of the *jointless algæ*, of which 160 species are known as natives of the British Isles. In the manufacture of Kelp (See KELP), all the varieties of this division may be used. The edible sorts, such as the birds' nests of the Eastern Archipelago, those which we consume in this country, as *lavers*, carrageen, or Irish moss, &c., belong to the same group, as do also those which the agriculturalists employ for manure.

Dr. Pereira gives the following list of esculent seaweeds.

Rhodomenia palmata (or Dulse).	*Iridæa edulis.*
Rhodomenia ciliata.	*Alaria esculenta*
Laminaria saccharina.	*Ulva latissima.*

Rhodomenia palmata passes under a variety of names, dulse, dylish, or dellish, and amongst the Highlanders it is called *dulling*, or waterleaf. It is employed as food by the poor of many nations; when well washed, it is chewed by the peasantry of Ireland without being dressed. It is nutritious, but sudorific, has the smell of violets, imparts a mucilaginous feel to the mouth, leaving a slightly acrid taste. In Iceland the dulse is thoroughly washed in fresh water and dried in the air. When thus treated it becomes covered with a white powdery substance, which is sweet and palatable; this is *mannite* (see MANNA), which Dr. Stenhouse proposes to obtain from seaweeds. "In the dried state it is used in Iceland with fish and butter, or else, by the higher classes: boiled in milk with the addition of rye flour. It is preserved packed in close casks, a fermented liquor is produced in Kamschatka from this seaweed, and in the North of Europe and in the Grecian Archipelago cattle are fed upon it."—*Stenhouse.*

Laminaria saccharina yields 12·15 per cent. of mannite, while the *Rhodomenia palmata* contains not more than 2 or 3 per cent.

Iridæa edulis.—The fronds of this weed are of a dull purple colour, flat, and succulent. It is employed as food by fishermen, either raw or pinched between hot irons, and its taste is then said to resemble roasted oysters.

Alaria esculenta.—Mr. Drummond informs us that, on the coast of Antrim, "it is often gathered for eating, but the part used is the leaflets, and not the midrib, as is commonly stated. These have a very pleasant taste and flavour, but soon cover the mouth with a tenacious greenish crust, which causes a sensation somewhat like that of the fat of a heart or kidney."

Ulva latissima (Broad green laver).—This is rarely used, being considered inferior to the *Porphyra laciniata* (Laciniated purple laver). This alga is abundant on all our shores. It is pickled with salt, and sold in England as *laver*, in Ireland as *sloke*, and in Scotland as *slaak*. The London shops are mostly supplied with laver from the coasts of Devonshire. When stewed, it is brought to the table and eaten with pepper, butter or oil, and lemon-juice or vinegar. Some persons stew it with leeks and onions. The pepper dulse (*Laurencia pinnatifida*), distinguished for its pungent taste, is often used as a condiment when other seaweeds are eaten. "Tangle" (*Laminaria digitata*), so called in Scotland, is termed "red-ware" in the Orkneys, "sea-wand" in the Highlands, and "sea-girdles" in England. The flat leathery fronds of this weed, when young, are

Digitized by Google

employed as food. Mr. Simmonds tells us, "There was a time when the cry of 'Buy dulse and tangle' was as common in the streets of Edinburgh and Glasgow, as is that of 'water-cresses' now in our metropolis."—*Society of Arts' Journal.*

Laminaria potatorum. — The large sea tangle is used abundantly by the inhabitants of the Straits of Magellan and by the Fuegians. Under the name of "Bull Kelp" it is used as food in New Zealand and Van Diemen's Land. It is stated to be exceedingly nutritive and fattening.

Chondrus crispus (chondrus, from χόνδρος, cartilage).—Carrageen, Irish, or pearl moss. For purposes of diet and for medicinal uses, this alga is collected on the west coast of Ireland, washed, bleached by exposure to the sun, and dried. It is not unfrequently used in Ireland by painters and plasterers as a substitute for size. It has also been successfully applied, instead of isinglass, in making of blanc-mange and jellies; and in addition to its use in medicine, for which purpose it was introduced by Dr. Todhunter, of Dublin, about 1831, a thick mucilage of carrageen, scented with some prepared spirit, is sold as *bandoline, fixature,* or *clysphitique,* and it is employed for stiffening silks. According to Dr. Davy, carrageen consists of

Gummy matter	28·5
Gelatinous matter	49·0
Insoluble matter	22·5
	100·0

The following results, obtained by Dr. Apjohn and Dr. Davy, show, in a satisfactory manner, the value of the algæ. The amount of water is less than that which belongs to the algæ when fresh from the sea, all these having undergone a partial drying in the progress of carriage from the coast:—

Specimens supplied by Dr. Davy, and dried at 212° —

	Nitrogen per cent.
Chondrus crispus, bleached	2·152
Fucus vesiculosus	2·397
Rhodomenia palmata (Dylisk)	3·776

Kinds of Algæ.	Water.	Dry Matter.	Per Cent. of Nitrogen in Dry Matter.	Protein contained in Dry Matter.
Chondrus crispus, bleached	17·92	82·08	1·534	9·587
Chondrus crispus, unbleached, Ballycastle	21·47	78·53	2·142	13·387
Gigartina mammillosa, Ballycastle	21·55	78·45	2·198	13·737
Chondrus crispus, bleached (2nd experiment)	19·79	80·21	1·485	9·281
Chondrus crispus, unbleached, Ballycastle, (2nd experiment)	19·96	80·04	2·510	15·687
Laminaria digitata, or Dulse tangle, Ballycastle	21·38	78·62	1·588	9·925
Laminaria digitata, or Black tangle, Ballycastle	31·05	68·95	1·396	8·725
Rhodomenia palmata, or Dylisk, Ballycastle	16·56	83·44	3·465	21·656
Porphyra laciniata, Ballycastle	17·41	82·59	4·650	29·062
Iridæa edulis, Ballycastle	19·61	80·39	3·088	19·300
Alaria esculenta, or Murlins, Ballycastle	17·91	82·09	2·424	15·150
Mean composition of these Algæ	20·42	79·58	2·407	15·045

The quantity of nitrogen contained in some of these plants is remarkably large, and will, of course, with the proteinaceous substances detected in all the Algæ, account for the high nutritive value ascribed to them.

Plocaria candida.—Ceylon moss; Edible moss. This moss is exported from the islands of the Indian Archipelago, forming a portion of the cargoes of nearly all the junks. It is stated by Mr. Crawford, in his "History of the Indian Archipelago," that on the spots where it is collected, the prices seldom exceed from 5*s.* 8*d.* to 7*s.* 6*d.* per cwt. The Chinese use it in the form of a jelly with sugar, as a sweatmeat, and apply it in the arts as an excellent paste. The gummy matter which they employ for covering lanterns, varnishing paper, &c., is made chiefly from this moss.

Digitized by Google

As ordinarily sold in Ceylon, it appears to consist of several varieties of marine productions, with the *Plocaria* intermixed.

The *Agar-Agar* of Malacca belongs to this variety; and probably seaweeds of this character are used by the Salangana or esculent swallow in constructing their nests, which are esteemed so great a delicacy by the Chinese. The plant is found on the rocks of Pulo Ticoos and on the shores of the neighbouring islands. It is blanched in the sun for two days, or until it is quite white. It is obtained on submerged banks in the neighbourhood of Macassar, Celebes, by the Bajow-laut, or sea-gipsies, who send it to China. It is also collected on the reefs and rocky submerged ledges in the neighbourhood of Singapore. Mr. Montgomery Martin informs us that Agar-Agar produces in China from six to eight dollars per peeul in its dry and bulky state. From 6,000 to 12,000 peculs are produced annually, the pecul being equal to 100 catties of 1·333 lbs. each.

Similar to this, perhaps the same in character, is the *Agal-Agal*, another species of seaweed. It dissolves into a glutinous substance, and its principal use is for gumming silks and paper, as nothing equals it for paste, nor is it liable to be eaten by insects. The Chinese make a beautiful kind of lantern formed of netted thread washed over with this gum, and which is extremely light and transparent.

Dr. Macgowan, of Ningpo, forwarded to the Society of Arts, through Sir John Bowring, the following algæ, which he thus names and describes:—

Tan-shwin grass, so named from the place, on the coast of Formosa, whence it is procured. It is used for making *yang-tsai* (ocean-vegetable).

Nin-mau (ox-hair) grass. Made into an iced jelly, and sold in the streets, in hot weather, sugared.

Hâi-tâi (sea-tape). Sent into the interior, wherever fossil coal is used. It is considered corrective of the deleterious exhalations of that fuel. It is usually boiled with pork. This kind comes from Shantung province.

Tsz-tsai (purple vegetable). Often eaten as it is, to give a relish to rice, or cooked.

Fah-tsai (hair vegetable). Boiled, either with animal or vegetable articles, forms a broth. Also the gills eaten with sugar.

Ki-tsai (hen-foot vegetable). Cooked with soy or vinegar. Used by women to make the hair glossy, and to strengthen it.

Sea-tape, from Japan. It is preferred to the former. — *Society of Arts' Journal.*

ALIMENT. (*Alimentum*, from *alo*, to feed.) The food necessary for the human body, and capable of maintaining it in a state of health.

1. Nitrogenous substances are required to deposit, from the blood, the organised tissue and solid muscle;

2. And carbonaceous, non-nitrogenous bodies, to aid in the processes of respiration, and in the supply of carbonaceous elements, as fat, &c., for the due support of animal heat.

For information on these substances, consult Liebig's "Animal Chemistry," the investigations of Dr. Lyon Playfair, and Dr. Robert Dundas Thompson's "Experimental Researches on Food," 1846. See FOOD.

ALIZARINE. See MADDER.

ALKALI. A term derived from the Arabians, and introduced into Europe when the Mahometan conquerors pushed their conquests westward. Al, el, or ul, as an Arabic noun, denotes "God—Heaven—Divine." As an Arabic particle, it is prefixed to words to give them a more emphatic signification, much the same as our particle *the*; as in *Alcoran*, the Koran, *alchymist*, the chemist.

Kali was the old name for the plant producing potash (the glasswort, so called from its use in the manufacture of glass), and *alkali* signified no more than the kali plant. Potash and soda were for some time confounded together, and were hence called alkalis. Ammonia, which much resembles them when dissolved in water, was also called an alkali. Ammonia was subsequently distinguished as the *volatile alkali*, potash and soda being called *fixed alkalis*. Ammonia was also called the animal alkali; soda was the mineral alkali, being derived from rock-salt, or from the ocean; and potash received the name of vegetable alkali, from its source being the ashes of plants growing upon the land. Alkalis are characterised by being very soluble in water, by neutralising the strongest acids, by turning to brown the vegetable yellows, and to green the vegetable reds and blues.

Some chemists classify all salifiable bases under this name.

In commercial language, the term has been hitherto applied to an impure soda, but now it is understood to comprehend both soda and potash. The imports and exports of the alkalis are given on the opposite page. See POTASH and SODA.

ALKALI, ORGANIC, or ALKALOID. During the last few years the organic alkaloids has so greatly increased, that a considerable volume might be devoted to their history. There are, however, only a few which have become articles of commerce. The modes of preparation will be given under the heads of the alkalis themselves. The principal sources from whence they are obtained are the following:—1. The animal kingdom. 2. The vegetable kingdom. 3. Destructive distillation. 4. The action of potash on the cyanic and cyanuric ethers. 5. The action of ammonia on the iodides, &c., of the alcohol radicals. 6. The action of reducing agents on nitro-compounds. The principal bases existing in the animal kingdom are creatine and sarcosine. The vegetable kingdom is much richer in them, and yields a great number of organic alkalis, of which several are of extreme value in medicine. Modern chemists regard all organic alkalis as derived from the types ammonia or oxide of ammonium. Their study has led to results of the most startling character. It has been found that not only may the hydrogen in ammonia and oxide of ammonium be replaced by metals and compound radicals without destruction of the alkaline character, but even the nitrogen may be replaced by phosphorus or arsenic, and yet the resulting compounds remain powerfully basic. In studying the organic bases, chemists have constantly had in view the artificial production of the bases of cinchona bark. It is true that this result has not as yet been attained; but, on the other hand, bodies have been formed having so many analogies, both in constitution and properties, with the substances sought, that it cannot be doubted the question is merely one

Digitized by Google

of time. The part performed by the bases existing in the juice of flesh has not been ascertained, and no special remedial virtues have been detected in them; but this is not the case with those found in vegetables; it is, in fact, among them that the most potent of all medicines are found — such, for example, as quinine and morphia. It is, moreover, among vegetable alkaloids that we find the substances most inimical to life, for aconitine, atropine, brucine, coniine, curarine, nicotine, solanine, strychnine, &c. &c., are among their number. It must not be forgotten, however, that, used with proper precaution, even the most virulent are valuable medicines. The fearfully poisonous nature of some of the organic bases, together with an idea that they are difficult to detect, has unhappily led to their use by the poisoner; strychnine, especially, has acquired a painful notoriety, in consequence of its employment by a medical man to destroy persons whose lives he had insured. Fortunately for society, the skill of the analyst has more than kept pace with that of the poisoner; and without regarding the extravagant assertions made by some chemists as to the minute quantities of vegetable poisons they are able to detect, it may safely be asserted that it would be very difficult to administer a fatal dose of any ordinary vegetable poison without its being discovered. Another check upon the poisoner is found in the fact that those most difficult of isolation from complex mixtures are those which cause such distinct symptoms of poisoning in the victim, that the medical attendant, if moderately observant, can scarcely fail to have his suspicions aroused.

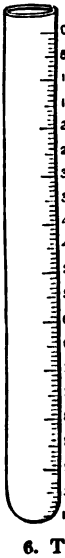
Under the heads of the various alkaloids will be found (where deemed of sufficient importance), not merely the mode of preparation, but also the easiest method of detection.—C. G. W.

ALKALIMETER. There are various kinds of alkalimeters, but it will be more convenient to explain their construction and use in the article on ALKALIMETRY, to which the reader is referred.

ALKALIMETRY. 1. The object of alkalimetry is to determine the quantity of caustic alkali or of carbonate of alkali contained in the potash or soda of commerce. The principle of the method is, as in acidimetry, based upon Dalton's law of chemical combining ratios — that is, on the fact that in order to produce a *complete reaction* a certain definite weight of reagent is required, or, in other words, in order to saturate or completely neutralise, for example, one equivalent of a base, exactly one equivalent of acid must be employed, and *vice versâ*. This having been thoroughly explained in the article on ACIDIMETRY, the reader is referred thereto.

2. The composition of the potash and of the soda met with in commerce presents very great variations; and the value of these substances being, of course, in proportion to the quantity of real alkali which they contain, an easy and rapid method of determining that quantity is obviously of the greatest importance both to the manufacturer and to the buyer. The process by which this object is attained, though originally contrived exclusively for the determination of the intrinsic value of these two alkalies (whence its name, Alkalimetry) has since been extended to that of ammonia and of earthy bases and their carbonates, as will be shown presently.

22



3. Before, however, entering into a description of the process itself, we will give that of the instrument employed in this method of analysis, which instrument is called an *alkalimeter*.

4. The common alkalimeter is a tube closed at one end (see figure in margin), of about $\frac{3}{4}$ths of an inch internal diameter, about $9\frac{1}{2}$ inches long, and is thus capable of containing 1000 grains of pure distilled water. The space occupied by the water is divided accurately into 100 divisions, numbering from above downwards, each of which, therefore, represents 10 grains of distilled water.

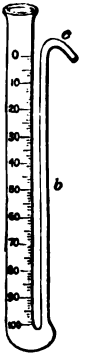
5. When this alkalimeter is used, the operator must carefully pour the acid from it by closing the tube with his thumb, so as to allow the acid to trickle in drops as occasion may require; and it is well also to smear the edge of the tube with tallow, in order to prevent any portion of the test acid from being wasted by running over the outside after pouring, which accident would, of course, render the analysis altogether inaccurate and worthless; and, for the same reason, after having once begun to pour the acid from the alkalimeter by allowing it to trickle between the thumb and the edge of the tube, as above mentioned, the thumb must not be removed from the tube till the end of the experiment, for otherwise the portion of acid which adheres to it would, of course, be wasted and vitiate the result. This uncomfortable precaution is obviated in the other forms of alkalimeter now to be described.

6. That represented in *fig.* 23 is Gay-Lussac's alkalimeter; it is a glass tube about 14 inches high, and $\frac{1}{4}$ an inch in diameter, capable of holding more than 1000 grains of distilled water; it is accurately graduated from the top downwards into 100

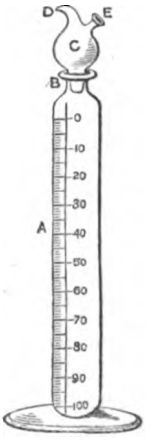
Digitized by Google

divisions, in such a way that each division may contain exactly 10 grains of water. It has a small tube, *b*, communicating with a larger one, which small tube is bent and bevelled at the top, *c*. This very ingenious instrument, known also under the names of "*burette*" and "*pouret*," was contrived by Gay-Lussac, and is by far more convenient than the common alkalimeter, as by it the test acid can be unerringly poured, drop by drop, as wanted. The only drawback is the fragility of the small side-tube, *b*, on which account the common alkalimeter, represented in *fig.* 22, is now generally used, especially by workmen, because as it has no side-tube it is less liable to be broken; but it gives less accurate results, a portion of the acid being wasted in various ways, and it is besides less manageable. Gay-Lussac's "burette" is therefore preferable; and if melted wax be run between the space of the large and of the small tube, the instrument is rendered much less liable to injury; it is generally sold with a separate wooden foot or socket, in which it may stand vertically.

23



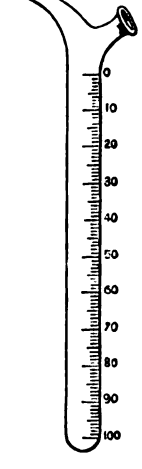
24



7. The following form of alkalimeter (*fig.* 24), which I contrived several years ago, will, I think, be found equally delicate but more convenient still than that of Gay-Lussac. It consists of a glass tube, A, of the same dimensions and graduated in the same manner as that of Gay-Lussac; but it is provided with a glass foot, and the upper part, B, is shaped like the neck of an ordinary glass bottle; C is a bulb blown from a glass tube, one end of which is ground to fit the neck, B, of the alkalimeter, like an ordinary glass stopper. This bulb is drawn to a capillary point at D, and has a somewhat large opening at E. With this instrument the acid is perfectly under the control of the operator, for the globular joint at the top enables him to see the liquor before it actually begins to drop out, and he can then regulate the pouring to the greatest nicety, whilst its more substantial form renders it much less liable to accidents than that of Gay-Lussac; the glass foot is extremely convenient, and is at the same time a great additional security. The manner of using it will be described further on.

8. Another alkalimeter of the same form as that which I have just described, except that it is all in one piece, and has no globular enlargement, is represented in *fig.* 25. Its construction is otherwise the same, and the results obtained are equally delicate; but it is less under perfect control, and the test acid is very liable to run down the tube outside: this defect might be easily remedied by drawing the tube into a finer and more delicate point, instead of in a thick blunted projection, from which the last drop cannot be detached, or only with difficulty and imperfectly. A glass foot would moreover be an improvement.

25



9. With Schüster's alkalimeter (represented in *fig.* 26), the strength of alkalis is determined by the *weight*, not by the *measure*, of the acid employed to neutralise the alkali: it is, as may be seen, a small bottle of thin glass having the form of the head of the alkalimeter represented in *fig.* 24. We shall describe further on the process of analysis with this alkalimeter.

10. There are several other forms of alkalimeter, but those which have been alluded to are almost exclusively used, and whichever of them is employed the process is the same—namely, pouring carefully an acid of a known strength into a known weight of the alkali under examination, until the neutralising point is obtained, as will be fully explained presently.

26

11. Blue litmus-paper being immediately reddened by acids is the reagent used for ascertaining the exact point of the neutralisation of the alkali to be tested. It is prepared by pulverising one part of commercial litmus, and digesting it in six parts of cold water, filtering, and dividing the blue liquid into two equal portions, adding carefully to one of the portions, and *one drop* at a time, as much very dilute sulphuric acid as is sufficient to impart to it a slight red colour, and pouring the portion so treated into the second portion, which is intensely blue, and stirring the whole together. The mixture so obtained is neutral,

Digitized by Google

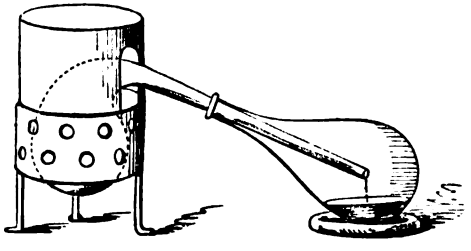
and by immersing slips of white blotting-paper into it, and carefully drying them by hanging them on a stretched piece of thread, an exceedingly sensitive test paper of a light blue colour is obtained, which should be kept in a wide-mouth glass-stoppered bottle, and sheltered from the air and light.

12. Since the principle on which alkalimetry is based consists in determining the amount of acid which a known weight of alkali can saturate or neutralise, it is clear that any acid having this power can be employed.

13. The test acid, however, generally preferred for the purpose is sulphuric acid, because the normal solution of that acid is more easily prepared, is less liable to change its strength by keeping, and has a stronger reaction on litmus-paper than any other acid. It is true that other acids — tartaric acid, for example — can be procured of greater purity, and that as it is dry and not caustic, the quantities required can be more comfortably and accurately weighed off; and on this account some chemists, after Buchner, recommended its use, but the facility with which its aqueous solution becomes mouldy is so serious a drawback, that it is hardly ever resorted to for that object.

14. When sulphuric acid is employed, the *pure* acid in the maximum state of concentration, or, as it is called by chemists, the *pure* hydrate of sulphuric acid, specific gravity 1·8485, is preferable. Such an acid, however, is never met with in commerce, for the ordinary English oil of vitriol is seldom pure, and never to the maximum state of concentration; the operator, however, may prepare it by distilling ordinary oil of vitriol, but as the specific caloric of the vapour of sulphuric acid is very small, the distillation is a somewhat hazardous operation, unless peculiar precaution be taken. The following apparatus, however, allows of the acid being distilled in a perfectly safe and convenient manner; it consists of a plain glass retort, charged with oil of vitriol, a little protosulphate of iron is added, for the purpose of destroying any nitrous products which the acid may evolve, and it is then placed into a cylinder of iron, the bottom of which is perforated with holes about three quarters of an inch in diameter, except in the middle, where a large hole is cut of a suitable size for the retort to rest upon; the sides of the cylinder are likewise perforated, as represented in *fig.* 27. Ignited charcoal is then placed all round the retort, the bottom of which protruding out of the influence of the heat, allows the ebullition to proceed from the sides only. It is well to put into the retort a few fragments of quartz or a few lengths of platinum wire, the effect of which is to render the ebullition more regular

27



15. In order to prevent the acid fumes from condensing in the neck of the retort, it should be covered with a cover of sheet iron, as represented in *fig.* 27.

16. The first fourth part which distils over should be rejected, because it is too weak; the next two fourths are kept, and the operation is then stopped, leaving the last fourth part of the acid in the retort. The neck of the retort should be about four feet long and about one and a half inches in the bore, and be connected with a large receiver; and as the necks of retorts are generally much too short for the purpose, an adapter tube should be adjusted to it and to the receiver, but very loosely; this precaution is absolutely necessary, for otherwise the hot acid falling on the sides of the receiver would crack it; things, in fact, should be so arranged that the hot drops of the distilling acid may fall into the acid which has already distilled over. Do not surround the receiver with cold water, for the hot acid dropping on the refrigerated surface would also certainly crack it. The acid so obtained is pure oil of vitriol, or monohydrated sulphuric acid, SO^3, HO, and it should be kept in a well stoppered and dry flask.

17. For commercial assays, however, and, indeed, for every purpose, the ordinary concentrated sulphuric acid answers very well: when used for the determination of the value of potashes, it is made of such a strength that each division (or 10 water-grains' measure) of the alkalimeter saturates exactly one grain of pure potash: an acid of that particular strength is prepared as follows: —

18. Take 112·76 grains of pure neutral and anhydrous carbonate of soda, and dissolve them in about 5 fluid ounces of hot water.* This quantity, namely, 112·76

* Anhydrous, or dry, neutral carbonate of soda may be obtained by keeping a certain quantity of pure bicarbonate of soda for a short time, at a dull red heat, in a platinum crucible: the bicarbonate is converted into its neutral carbonate, of course free from water.

Digitized by Google

grains, of neutral carbonate of soda will exactly saturate the same quantity of pure sulphuric acid (SO^3) that 100 grains of pure potash would. It is advisable, however, to prepare at once a larger quantity of test solution of carbonate of soda, which is of course easily done, as will be shown presently.

19. Mix, now, 1 part, by measure, of concentrated sulphuric acid with 10 parts of water, or rather—as it is advisable, where alkalimetrical assays have frequently to be made, to keep a stock of test acid—mix 1000 water-grains' measure of concentrated sulphuric acid with 10,000 grains of water, or any other larger proportions of concentrated sulphuric acid and water, in the above respective proportions; stir the whole well, and allow it to cool. The mixture of the acid with the water should be made by first putting a certain quantity of the water into a glass beaker or matrass of a suitable size, then pouring the concentrated acid slowly therein, while a gyratory motion is imparted to the liquid. The vessel containing the acid is then rinsed with the water, and both the rinsing and the rest of the water are then added to the whole mass. When quite cold, fill the graduated alkalimeter with a portion of it up to the point marked 0°, taking the under line of the liquid as the true level; and, whilst stirring briskly with a glass rod the aqueous solution of the 112·76 grains of neutral carbonate of soda above alluded to, drop the test acid from the alkalimeter into the vortex produced by stirring, until, by testing the alkaline solution with a strip of reddened litmus-paper after every addition of acid, it is found that it no longer shows an alkaline reaction (which is known by the slip of reddened litmus-paper not being rendered blue), but, on the contrary, indicates that a very slight excess of acid is present (which is known by testing with a slip of blue litmus-paper, which will then turn slightly red).

20. If, after having exhausted the whole of the 100 divisions (1000 water-grains' measure) of the diluted acid in the alkalimeter, the neutralisation is found to be *exactly* attained, it is a proof that the test acid is right.

21. But suppose, on the contrary (and this is a much more probable case), suppose that only 80 divisions of the acid in the alkalimeter have been required to neutralise the alkaline solution, it is then a proof that the test acid is too strong, and accordingly it must be further diluted with water, to bring it to the standard strength; and this may at once be done, in the present instance, by adding 20 measures of water to every 80 measures of the acid. This is best accomplished by pouring the whole of the acid into a large glass cylinder, divided into 100 equal parts, until it reaches the mark or scratch corresponding to 80 measures; the rest of the glass, up to 100, is then filled up with water, so that the same quantity of real acid will now be in the 100 measures as was contained before in 80 measures.

22. The acid adjusted as just mentioned should be labelled "*Test Sulphuric Acid for Potash*," and kept in well-stoppered bottles, otherwise evaporation taking place would render the remaining bulk more concentrated, consequently richer in acid than it should be, and it would thus, of course, become valueless as a test acid until re-adjusted. Each degree or division of the alkalimeter of such an acid represents 1 grain of pure potash.

23. The alkalimetrical *assay of soda* is also made with sulphuric acid, in preference to other acids, but it must be so adjusted that 100 alkalimetrical divisions (1000 water-grains' measure) of acid will exactly neutralise 170·98 of pure anhydrous carbonate of soda, that quantity containing 100 grains of pure soda.

24. Dissolve, therefore, 171 grains of pure anhydrous neutral carbonate of soda, obtained as indicated before, in five or six ounces of hot water, and prepare in the meantime the test sulphuric acid, by mixing 1 part, by measure, of ordinary concentrated sulphuric acid, with about 9 parts by measure of water exactly as described before; stir the whole thoroughly, let the mixture stand until it has become quite cold, then pour 1000 water-grains' measure of the dilute acid so prepared into an alkalimeter—that is to say, fill that instrument up to 0°, taking the under line as the true level, and then, whilst stirring briskly the aqueous solution of the 171 grains of carbonate of soda with a glass rod, pour the acid, with increased precaution as the saturating point is approaching, into the vortex produced, until by testing the liquor alternately with reddened and with blue litmus-paper, or with grey litmus-paper, as before mentioned, the exactly neutralised point is hit.

25. If the whole of the 100 alkalimetrical divisions (1000 water-grains' measure) have been required to effect the neutralisation, it is a proof that the acid is of the right strength, but if this be not the case, it must be adjusted as described before—that is to say:—

26. Suppose, for example, that only 75 alkalimetrical divisions or measures of the acid in the alkalimeter have been required to neutralise the 171 grains of neutral carbonate of soda operated upon, then 75 measures of the acid should be poured at once into a glass cylinder accurately divided into 100 parts; the remaining 25 divisions

Digitized by Google

should then be filled with water, and the whole being now stirred up, 100 parts of the liquor will of course contain as much real acid as 75 parts contained before, and accordingly the acid may now be used as a test acid for the alkalimetrical assay of soda, each degree or division of the alkalimeter representing one grain of pure soda.

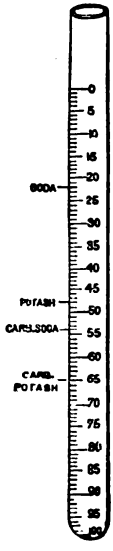
27. The stock of test acid should be kept in well-stoppered flasks, that it may not vary in strength by evaporation, and be labelled "*Test Sulphuric Acid for Soda.*"

28. Instead however of keeping two kinds of "test sulphuric acid," of different saturating powers as described, the one for *potash*, the other for *soda*, one kind only may be prepared so as to serve for both alkalis, by constructing, as is very often done, an alkalimeter adjusted so as to indicate the quantities of the acid of a given strength required for the saturation or neutralisation of both potash or soda, or of their respective carbonates; and this, in fact, is the alkalimeter most in use in the factory.

It should be in shape similar to that of Gay-Lussac's (see *fig.* 23), or that described in *figs.* 24 and 25; but, like that represented by *fig.* 22, it generally consists of a tube closed at one end, about three-fourths of an inch internal diameter and about 9½ inches in length; it is graduated into 100 equal parts, and every division is numbered from above downwards (*see fig.* 28).

The following directions for their construction are given by Professor Faraday. "Let the tube represented in the margin have 100° grains of water weighed into it; then let the space it occupies be graduated into 100 equal parts, and every ten divisions numbered from above downwards. At 22·1 parts, or 77·99 parts from the bottom, make an extra line, a little on one side or even on the opposite side of the graduation, and write at it with a scratching diamond, *soda*; lower down, at 48·62 parts, make another line, and write *potash*; still lower, at 54·43 parts, a third line marked *carb. soda*, and at 65 parts a fourth, marked *carb. potash*. It will be observed that portions are measured off beneath these marks in the inverse order of the equivalent number of these substances, and consequently directly proportionate to the quantities of any particular acid which will neutralise equal weights of the alkalis and their carbonates. As these points are of great importance, it will be proper to verify them by weighing into the tubes first 350, then 513·8, and lastly 779·9 grains of water, which will correspond with the marks if they are correct, or the graduation may be laid down from the surface of the four portions of fluid when weighed in, without reference to where they fall upon the general scale. The tube is now completed, except that it should be observed whether the aperture can be perfectly and securely covered by the thumb of the left hand, and if not, or if there be reason to think it not ultimately secure, then it should be heated and contracted until sufficiently small."

28



29. The test acid for this alkalimeter should have a specific gravity of 1·1268; and such an acid may be prepared by mixing one part, by weight, of sulphuric acid, specific gravity 1·82, with four parts of water, and allowing the mixture to cool. In the meantime, 100 grains of pure anhydrous carbonate of soda, obtained as indicated before, should be dissolved in water, and the test sulphuric acid, of specific gravity 1·1268, prepared as abovesaid, having become quite cold, is poured into the alkalimeter up to the point marked carbonate of soda, the remaining divisions are filled up with water, and the whole should be well mixed by shaking.

30. If the whole of the sulphuric acid, adjusted as was said, being poured carefully into the solution of the 100 grains of the neutral carbonate of soda, neutralise them exactly — which is ascertained, as usual, by testing the solution with litmus-paper, which should not be either reddened or rendered bluer by it — it is of course a sign that the test is as it should be—that is to say, is of the proper strength; in the contrary case it must be finally adjusted in the manner already indicated, and which need not be repeated. See §§ 20, 21.

31. The best and most convenient process for the analyst, however, consists in preparing a test acid of such a strength that it may serve not only for all alkalis, but indeed for every base; that is to say, by adjusting the test acid so that 100 alkalimetrical divisions of it (1000 water-grains' measure) may exactly saturate or neutralise one equivalent of every base. This method, which was first proposed by Dr. Ure, is exceedingly convenient, and the possession of two reciprocal test liquids, namely the ammonia test liquor of a standard strength, of which we gave a description in the article on Acidemetry, and the standard test acid of which we are now speaking, affords, as Dr. Ure observes, ready and rigid means of verification. For microscopic analysis of alkaline and of acid matter, a graduated tube of a small bore, mounted in a frame, with a valve apparatus at top, so as to let fall drops of any size

Digitized by Google

and at any interval, is desirable; and such an instrument Dr. Ure employed for many years; but instead of a tube with a valve apparatus at top, the operator may use a graduated tube of a small bore, terminated by a small length of vulcanised india-rubber tube pinched in a clamp, which may be relaxed in such a way as to permit also the escape of drops of any size at any interval of time, the little apparatus being under perfect command.

32. The test sulphuric acid, of such a strength that 100 alkalimetrical divisions of it can saturate one equivalent of every base, should have a specific gravity of 1·032, and is prepared as follows: —

Take 53 grains (one equivalent) of pure anhydrous neutral carbonate of soda, obtained in the manner indicated before (see § 18), and dissolve them in about one fluid ounce of water. Prepare, in the meantime, the test sulphuric acid by mixing one part, by measure, of concentrated sulphuric acid with about 11 or 12 parts of water, and stir the whole well. The mixture having become quite cold, fill the alkalimeter with the cold diluted acid up to the point marked 0°, taking the under line of the liquid as the true level, and, whilst stirring briskly the aqueous solution of the 53 grains of carbonate of soda above alluded to, pour the acid carefully from the alkalimeter into the vortex produced by stirring, until, by testing the liquor alternately with reddened and with blue litmus-paper, or, more conveniently still, with grey litmus-paper, the neutralising point is exactly hit.

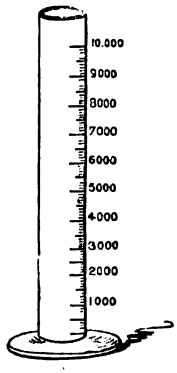
33. If the whole of the 100 divisions of the alkalimeter had been required to neutralise exactly the 53 grains of pure anhydrous carbonate of soda, it would be a proof that the acid is of the right strength; but if this is not the case, it must be adjusted in the manner described before, that is to say: —

34. Let us suppose, for example, that only 50 measures in the alkalimeter have been required to saturate or neutralise the 53 grains of carbonate of soda, then 50 measures should be poured at once into a glass cylinder accurately divided into 100 parts, the remaining 50 divisions should be filled up with water, and the whole being well stirred, 100 parts of the acid liquor will now contain as much real acid as was contained before in the 50 parts.

35. The acid may now be labelled simply, "*Test or Normal Sulphuric Acid.*" Each one hundred alkalimetrical divisions, or 1000 water-grains' measure of it, contain one equivalent, or 40 grains of real sulphuric acid; and, consequently, each 100 alkalimetrical divisions of it will neutralise one equivalent, or 31 grains of soda, 47 of potash, 17 of ammonia, 28 of lime, and so forth, with respect to any other base.

36. The stock of test or normal sulphuric acid should, as usual, be kept in well-stoppered bottles, in order to prevent concentration by evaporation. By keeping in the flask containing it a glass bead, exactly adjusted to the specific gravity of 1·032, the operator may always ascertain, at a glance, whether the acid requires readjusting.

37. With a Schüster's alkalimeter, it is convenient to prepare the test acid of such a strength that, according as it has been adjusted for potash or for soda, 10 grains of it will exactly saturate one grain of one or the other of these bases in a pure state. It is considered that the alkalimeter may be charged with a known weight of any of the other sulphuric test acids of a known strength. Suppose, for example, that the test sulphuric acid taken have a specific gravity of 1·032, we know, as we have just shown, that 1·032 grains weight of that acid contains exactly one equivalent of pure sulphuric acid = 40, and is capable, therefore, of neutralising one equivalent of any base; and, consequently, by taking a certain weight of this acid before beginning the assay, and weighing what is left of it after the assay, it is very easy to calculate, from the quantity of acid consumed in the experiment, what quantity of base has been neutralised. Thus a loss of 21·96 – 60·70 – 33·29 grains weight of this test acid represents one grain of potash, of ammonia, of soda respectively, and so on with the other bases.



38. The operator being thus provided with an appropriate test acid, we shall now describe how he should proceed with each of them in making an alkalimetrical assay with potash.

In order to obtain a reliable result, a fair average sample must be operated upon. To secure this the sample should be taken from various parts of the mass and at once put in a wide-mouth bottle, and well corked up until wanted; when the assay has to be made, the contents of the bottle must be reduced to powder, so as to obtain a fair mixture of the whole; of this weigh out 1000 grains exactly—or less, if that quantity cannot be spared—and dissolve them in a porcelain capsule in about 8 fluid ounces of distilled hot water, or in that proportion; and if there be left anything like an insoluble residue, filter, in order to separate it, and wash it on the

Digitized by Google

filter with small quantities of distilled water, and pour the whole solution, with the washings and rinsings, into a measure divided into 10,000 water-grains' measure. If the water used for washing the insoluble residue on the filter has increased the bulk of the solution beyond 10,000 water-grains' measure, it must be reduced by evaporation to that quantity; if, on the contrary, the solution poured in the measure stands below the mark 10,000 water-grains' measure, then as much water must be added thereto as will bring the whole mass exactly to that point. In order to do this correctly, the cylindrical measure should stand well on a table, and the under or lower line formed by the liquid, as it reaches the scratch 10,000, is taken as the true level.

39. This being done, 1000 grains' measure of the filtrate, that is to say, *one-tenth* part of the whole solution, is transferred to a glass beaker, in which the saturation or neutralisation is to be effected, which is best done by means of a pipette capable of containing exactly that quantity when filled up to the scratch, *a*. In order to fill such a pipette it is sufficient to dip it into the alkaline solution and to suck up the liquor a little above the scratch, *a*; the upper orifice should then be stopped with the first finger, and by momentarily lifting it up, the liquor is allowed slowly to fall from the pipette back again into the 10,000 grains' measure until its level reaches exactly the scratch, *a*. The last drop which remains hanging from the point of the pipette may be readily detached by touching the sides of the glass measure with it. The 1000 grains being thus rigorously measured in the pipette should then be transferred to the glass beaker, in which the neutralisation is to take place, by removing the finger altogether, blowing into it to detach the last drop, and rinsing it with a little water.

40. Or, instead of the pipette just described, the operator may measure 1000 grains by taking an alkalimeter full of the alkaline solution, and emptying it into the glass beaker in which the neutralisation is to take place, rinsing it with a little water, and of course adding the rinsing to the mass in the said glass beaker.

41. Whichever way is adopted, a slight blue colour should be imparted to the 1000 grains' measure of the alkaline solution, by pouring into it a small quantity of tincture of litmus. The glass beaker should then be placed upon a sheet of white paper, or a slab of white porcelain, in order that the change of colour produced by the gradual addition of the test acid may be better observed.

42. This being done, if the operator have decided upon using the *test sulphuric for potash* (§§ 17-22), he should take one of the alkalimeters, represented in *figs.* 22, 23, 24, or 25, and fill it up to 0° (taking the under line of the liquid as the true level); then taking the alkalimeter thus charged in his right hand, and in his left the glass beaker containing the alkaline solution coloured blue by tincture of litmus, he should gradually and carefully pour the acid liquor into the alkaline solution in the glass beaker, to which a circular motion should be given whilst pouring the acid, or which should be briskly stirred, in order to insure the rapid and thorough mixing of the two liquors, and therefore their complete reaction; moreover, in order at once to detect any change of colour from blue to red, the glass beaker should be kept over the white sheet of paper or the white porcelain slab, as before stated.

43. At first no effervescence is produced, because the carbonic acid expelled, instead of escaping, combines with the portion of the alkaline carbonate as yet undecomposed, which it converts into bicarbonate of potash, and accordingly no sensible change of colour is perceived; but as soon as a little more than half the quantity of the potash present is saturated, the liquor begins to effervesce, and the blue colour of the solution is changed into one of a vinous, that is, of a purple or bluish-red hue, which is due to the action of the carbonic acid upon the blue colour of the litmus. More acid should be still added, but from this moment with very great care and with increased caution, gradually as the point of neutralisation is approached, which is ascertained by drawing the glass rod used for stirring the liquor across a slip of blue litmus-paper. If the paper remains blue, or if a red or reddish streak is thereby produced which disappears on drying the paper and leaves the latter blue, it is a proof that the neutralisation is not yet complete, and that the reddish streak was due only to the action of the carbonic acid; more acid must accordingly be poured from the alkalimeter, but one drop only at a time, stirring after each addition, until at last the liquor assumes a distinct red or pink colour, which happens as soon as it contains an extremely slight excess of acid; the streaks made now upon the litmus-paper will remain permanently red, even after drying, and this indicates that the reaction is complete and that the assay is finished.

44. If the potash under examination were perfectly caustic, the solution would suddenly change from blue to pink, because there would be no evolution of carbonic acid at all, and consequently no vinous or purple colour produced; if, on the other hand, the potash was altogether in the state of bicarbonate, the first drops of test

Digitized by Google

acid would at once decompose part of it and liberate carbonic acid, and impart a vinous colour to the solution at the very outset, which vinous colour would persist as long as any portion of the bicarbonate would remain undecomposed.

45. The neutralising point being attained, the operator allows the sides of the alkalimeter to drain, and he then reads off the number of divisions which have been employed. If, for example, 50 divisions have been used, then the potash examined contained 50 per cent. of real potash. See observ., § 48–49.

46. Yet it is advisable to repeat the assay a second time, and to look upon this first determination only as an approximation which enables the operator, now that he knows about where the point of neutralisation lies, to arrive, if need be, by increased caution as he reaches that point, at a much greater degree of precision. He should accordingly take again an alkalimeter full (1000 water-grains' measure) — that is to say, another tenth part of the liquor left in the 10,000 grains' measure — and add thereto at once 48 or 49 alkalimetrical divisions of the test acid, and after having thoroughly agitated the mixture, proceed to pour the acid carefully, two drops only at a time, stirring after such addition, and touching a strip of litmus-paper with the end of the glass rod used for stirring; and so he should go on adding two drops, stirring, and making a streak on the litmus-paper, until the liquor assumes suddenly a pink or onion-red colour, and the streak made on the litmus-paper is red also. The alkalimeter is then allowed to drain as before, and the operator reads off the number of divisions employed, from which number 2 drops (or $\frac{1}{10}$ths of a division) should be deducted; Gay-Lussac having shown that, in alkalimetrical assays, the sulphates of alkalis produced *retard* the manifestation of the red colour in that proportion. One alkalimetrical division generally consists of 10 drops, but as this is not always the case, the operator should determine for himself how many drops are necessary to make up one division, and take account of them in the assay according to the ratio thus found. In the example given before, and supposing 10 drops to form one alkalimetrical division, then the per-centage value of the sample of potash under examination would probably be as follows: —

Number of divisions of acid employed - - -	50·0
— 2 drops acid in excess - - - - -	0·2
Real per-centage of potash - - -	49·8

47. When the alkalimeter described in *fig.* 24 is employed, the test acid may, at the beginning of the experiment, be poured from the larger opening, E; but towards the end — that is, when the neutralising point is approaching — the acid should be carefully poured from the point, D, *in single drops, or only two drops at a time*, until the saturating point is hit, as we have just said. If the operator wishes to pour only one drop, he should close the larger opening, E, of the bulb with the thumb, and then fill the bulb with the test acid by inclining the alkalimeter; putting now the alkalimeter in an upright position, and removing the thumb, a certain quantity of acid will be retained in the capillary point, D; and if the thumb be now pressed somewhat forcibly against the opening, E, the acid contained in the capillary point will be forced out and form one drop, which will then fall into the alkaline solution if it be held over it. If the saturation be complete, the operator, without removing the bulb stopper, may, by applying his lips to the large opening, E, suck the acid engaged in the capillary point back into the alkalimeter.

48. If there should be in the mind of the operator any doubt as to what is meant by the onion-red colour which the liquor tinged blue with tincture of litmus acquires when slightly supersaturated, he may pour into a glass beaker a quantity of pure water equal to, or even larger than, the alkaline solution operated upon, and tinge it blue with a little tincture of litmus, to about the same degree of intensity as the alkaline liquor under examination. If he now pour into the pure water coloured blue with litmus, *one single drop* of the test acid, it will acquire at once, by stirring, the onion-red colour alluded to, and which he may now use as a standard of comparison.

49. Considering the rapidity with which these alkalimetrical operations can be performed, the operator, unless he have acquired sufficient practice, or unless a great degree of accuracy be not required, should repeat the assay two or three times, looking upon the first determination only as an approximation, and as a sort of guide as to the quantity of acid which will be required in the subsequent experiments, whereby he will now be enabled to proceed with increased caution as he approaches the point of saturation; but, at any rate, if he will not take the little extra trouble of a repetition, he should, before he begins to pour the acid, take a little of the filtered alkaline solution out of the glass beaker, as a *corps de réserve*, which he adds to the rest after the saturating point has been approximated, and from that moment he may proceed, but with great care, to complete the neutralisation of the whole.

Digitized by Google

50. Do not forget that as the test sulphuric acid *must always be added in slight excess* to obtain a distinct red streak on the litmus-paper, a correction is absolutely necessary; that is to say, the excess of sulphuric acid employed must be deducted if a strictly accurate result is sought.

51. If, instead of the special alkalimeter for potash above described, the operator prefers using that prepared of such a strength that 100 divisions of the alkalimeter (100 water-grains' measure) contain exactly one equivalent of each alkali or base, which test sulphuric acid, as we have seen, has a specific gravity of 1·032 (*see* §§ 31–36), he should proceed exactly as indicated in § 38, and following; and the alkalimeter being filled with that test acid, of specific gravity 1·032 up to 0°, it (the acid) should be poured carefully into the aqueous solution of the alkali tinged blue with litmus, until exact neutralisation is attained, precisely in the same manner as in § 38, and following.

52. The neutralising point being hit, let us suppose that the whole of the contents of the alkalimeter have been employed, that the aqueous solution tinged blue with litmus, is not yet saturated, and that, after having refilled the alkalimeter, the 4 divisions more (altogether 104 divisions) have been required to neutralise the alkali in the aqueous solution; then, since 100 divisions (1000 water-grains' measure) of the test acid now employed saturate exactly one equivalent, that is, 47 of potash, the question is now, What quantity of potash will have been saturated by the 104 divisions of acid employed? The answer is found, by a simple rule of proportion, to be nearly 49.

$$100 : 47 :: 104 : x = 48{\cdot}88.$$

The sample of potash examined contained, therefore, nearly 49 per cent. of pure potash.

53. If instead of the special test sulphuric acid for potash (§ 17), or of the test sulphuric acid for potash, soda, and other bases (§ 28), the operator uses the potash and soda alkalimeter (§§ 31–36), the method to be followed is exactly similar to that described in § 42 and following. Some of the test sulphuric acid, of specific gravity 1·1268, is to be poured into the alkalimeter until it reaches the point marked "*potash*" (that is to say, 48·62 divisions of the alkalimeter), taking the under line of the liquid as the true level, and the remaining divisions up to 0° are carefully filled with water. The operator then closes the aperture of the alkalimeter with the thumb of his left hand, and the whole is violently shaken so as to obtain a perfect mixture.

54. The acid so mixed must now be carefully poured from the alkalimeter into the alkaline solution of the potash under examination until neutralisation is attained, precisely as described § 42 and following.

55. The neutralising point being hit, the operator allows the sides of the alkalimeter to drain, and he then reads off the number of divisions employed in the experiment, which number indicates the per-centage of real potash contained in the sample.

56. Had the operator wished to estimate the quantity of potash as carbonate of potash, he should have poured the test acid into the alkalimeter up to the point marked "*carbonate of potash*," filled the remaining divisions of the alkalimeter up to 0° with water, and proceeding exactly as just mentioned, the number of divisions of acid employed would indicate the per-centage of potash contained in the sample as carbonate of potash.

57. If a *Schüster's alkalimeter* (*fig.* 26) be used, and supposing, for example, that the acid to be employed therewith is so adjusted that 10 grains *weight* of it neutralise exactly 1 grain in weight of potash, proceed as follows:—Take 100 grains in weight of a fair average of the sample, previously reduced to powder, dissolve them in water, filter with the precautions which have already been described before (§ 38 and following), and pour this solution into a glass cylinder graduated into 100 parts, and capable of containing 10,000 water grains; fill it up with water exactly as described before; of this take now 100 alkalimetrical divisions, that is to say, $\frac{1}{10}$th of the whole solution, and pour it in a glass beaker. On the other hand, charge the Schüster's alkalimeter with a certain quantity of the test acid, and weigh it, along with the alkalimeter itself, in a good balance. This done, proceed with the neutralisation of the solution in the glass beaker, by pouring the acid from the alkalimeter in the usual way, and with the usual precautions, until the saturation is completed. Replace the alkalimeter, with the quantity of unconsumed acid, in the scale of the balance, weigh accurately, and since every grain of acid represents $\frac{1}{10}$th of a grain of potash, the number of grains of acid used in the experiment indicates at once the per-centage of real potash present in the sample.

58. When, however, potash is mixed with soda, as is frequently the case with the potash of commerce, either accidentally or for fraudulent purposes, the determination of the amount of the cheaper alkali could not, until a comparatively recent period, be estimated, except by the expensive and tedious process of a regular chemical analysis.

Digitized by Google

In 1844, however, M. Edmund Pesier, professor of Chemistry at Valenciennes, published an easy and commercial method for the estimation of the quantity of soda which potash may contain, by means of an areometer of a peculiar construction, to which the name of "Natrometer" has been given by the talented professor.

59. The rationale of the method is grounded upon the increase of specific gravity which sulphate of soda produces in a solution saturated with pure sulphate of potash, and is deduced from the fact that a solution saturated with neutral sulphate of potash possesses a uniform and constant density when the saturation is made at the same temperature, and that the density of such a solution increases progressively in proportion to the quantity of sulphate of soda present; an increase of density so much the more readily observable, that the solubility of the sulphate of potash is greatly augmented by the presence of sulphate of soda. It had at first been thought that, in order to obtain anything like accuracy, it would be necessary to combine all the potash with one same acid, preferably sulphuric acid; and, consequently, that as the potash of commerce always contains a little, and sometimes a rather considerable quantity, of chloride of potassium, the latter salt should first be decomposed. Further experiments, however, established the fact, that in dissolving chloride of potassium in a saturated solution of sulphate of potash, the specific gravity of the liquor is not materially increased, since the introduction of as much as 50 per cent. of chloride of potassium does not increase that density more than 3 per cent. of soda would do when examined by the natrometer—a degree of accuracy quite sufficient for commercial purposes. When soda is added to a saturated solution of sulphate of potash, the further addition of chloride of potassium thereto renders the specific gravity of the liquor *less* than it would have been without that addition—an apparent anomaly due to the fact that chlorine, in presence of sulphuric acid, of potash, and of soda, combines with the latter base to form chloride of sodium; and it is this salt which increases the solubility of sulphate of potash, though in a somewhat less degree than sulphate of soda. Thus, if to a saturated solution of ulphate of potash 0·14 of soda be added along with 0·20 of chloride of potassium, the natrometer indicates only 0·125 of soda. Seeing, therefore, that in such an exceptional case the error does not amount to more than 0·015 of error, it will probably be found unnecessary in most cases to decompose the chloride contained in the potashes of commerce, that quantity being too small to materially affect the result. Yet, as the accurate determination of soda in potash was a great desideratum, M. Pesier contrived two processes, one of which, in the hands of the practised chemist, is as perfect as, but much more rapid than, those ordinarily resorted to; the other, which is a simplification of the first, yields results of sufficient accuracy for all commercial purposes.

60. *First process.*—Take 500 grains of a fair average sample of the potash to be examined, dissolve them in as little water as possible, filter, and wash the filter until the washings are no longer alkaline. This filtering, however, may be dispensed with when the potash is of good quality and leaves but a small residue, or when an extreme degree of accuracy is not required.

61. The potash being thus dissolved, a slight excess of sulphuric acid is added thereto; the excess is necessary to decompose the chlorides and expel the muriatic acid. The liquor so treated is then evaporated in a porcelain capsule, about six inches in diameter; and when it begins to thicken, it should be stirred with a glass rod, in order to avoid projections. When dry, the fire must be urged until the residue fuses, and it is then kept in a state of tranquil fusion for a few minutes. The capsule should then be placed upon, and surrounded with, hot sand, and allowed to cool down slowly, to prevent its cracking, which would happen without this precaution.

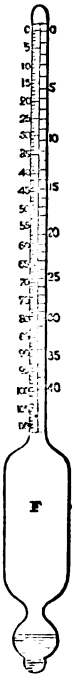
62. The fused mass in the capsule having become quite cold should now be treated with as little hot water as possible, that is to say, with less than 3000 grains of hot water; and this is best done by treating it with successive portions of fresh water. All the liquors thus successively obtained should then be poured into a flask capable of holding about 10,000 grains of water, and the excess of sulphuric acid *must be accurately neutralised* by a concentrated solution of pure carbonate of potash—that is to say, until the colour of litmus-paper is no longer affected by the liquor, just as in ordinary alkalimetrical or acidimetrical assays. During this operation, a pretty considerable precipitate of sulphate of potash is, of course, produced.

63. The neutralising point being exactly hit, a *saturated* solution of sulphate of potash is prepared, and brought to the atmospheric temperature; a condition which is expedited by plunging the vessel which contains the solution into a basin full of cold water, and stirring it until the thermometer plunged in the liquor indicates that the temperature of the latter is about the same as, and preferably less than, that of the air, because in the latter case it may be quite correctly adjusted by grasping the vessel with a warm hand. In order, however, to secure exactly the proper temperature, the whole should be left at rest for a few minutes after having withdrawn the

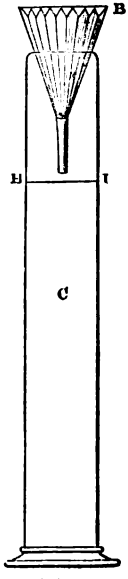
Digitized by Google

vessel from the basin of cold water used for refrigerating it, taking care simply to stir it from time to time, and to ascertain that the thermometer remains at the same degree of temperature. This done, the liquor is filtered into a glass cylinder, C, on which a scratch, H–I, has been made, corresponding to 3000 water-grains' measure. If the directions given have been exactly followed, it will be found that the filtrate is not sufficient to fill it up to that mark; the necessary volume, however, should be completed by washing the deposit of sulphate of potash in the filter, B, with a saturated solution of the same salt (sulphate of potash) *previously prepared*. It is advisable to use a saturated solution of sulphate of potash which has been kept for some time, and not one immediately prepared for the purpose, because sulphate of potash in dissolving produces a certain amount of cold, which would create delay, since it would be necessary to wait until the temperature of the mass had become the same as that of the air.

32



31



64. The liquor occupying 3000 water-grains' measure in the cylinder should be next rendered homogeneous by stirring it well, after which the natrometer may be immersed in it. The natrometer is simply an areometer of a peculiar construction, provided with two scales: the one of a pink colour shows the degrees of temperature, and indicates, for each degree of the centigrade thermometer, the level at which a solution saturated with pure sulphate of potash would stand; on the other scale, each degree represents 1 per cent. of soda (oxide of sodium), as represented in *fig.* 32.

65. The 0° of the two scales coincide with each other. If the experiment take place at the temperature of 0°, the quantity of soda will be directly determined by observing the number of degrees on the soda scale; but if the experiment be performed at 25°, for example, it will be seen that the point at which the instrument would sink in a liquor saturated with pure sulphate of potash corresponds to $\frac{8}{100}$th of soda, and, in this case, it is from *this point* that the 0° of the soda scale should be supposed to begin, which is easily accomplished by a simple subtraction, as will be seen presently.

66. Experiment having shown that the degrees of soda cannot be equidistant, but that, on the contrary, they become smaller and smaller as the quantity of soda increases, the number of degrees of soda are obtained as follows: —From the number of degrees of temperature now indicated *on the pink scale* of the natrometer, subtract the number of degrees of temperature indicated by an ordinary thermometer at starting; then look at the soda scale for the number of soda degrees which correspond to the number of degrees of temperature left after subtraction, and each of the soda degrees, beginning from the 0° of the natrometer, represents 1 per cent.

67. For example: —Suppose the experiment to have been made at starting, and as indicated by an ordnary thermometer, at + 20° centigrades, and that the level of the solution is now found to stand at 59° on the pink scale of temperature of the natrometer, then by deducting 20 (the original temperature) from 59 (number of degrees indicated by the floating point on the pink scale of temperatures of the natrometer) there remains, of course, 39. Draw the instrument out, and looking now on the said pink scale for 39°, there will be found exactly opposite, on the soda scale, the number 13, which number signifies that the potash under examination contains 13 per cent. of soda (oxide of sodium).

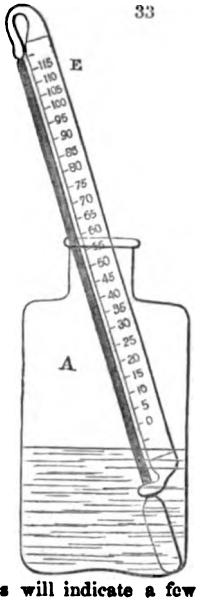
68. As the deposit of sulphate of potash separated by filtering might retain some sulphate of soda, it is advisable, in order to avoid all chance of error, to wash it with a saturated solution of sulphate of potash, adding as much of it as is necessary to bring the whole mass of the liquor up to the mark 3000 water-grains' measures, in which the natrometer being again immersed, the minute quantity of soda indicated should be added to the per-centage found by the first operation.

69. If a great degree of accuracy is required, the fractions of degree of the instrument must be taken account of; otherwise they may be neglected without the result being materially affected, since 3 degrees of the scale of temperature correspond only to about 1 per cent. of soda.

70. For commercial purposes, the process may be slightly varied, as follows: —Take 500 grains of a fair average sample of the potash to be examined, previously reduced to powder, and throw them into a flask, A (*fig.* 33), capable of containing about 6000 grains of water; pour upon them about 2000 grains of water, and shake until dissolved. Add now sulphuric acid thereto; this will produce a smart

Digitized by Google

effervescence, and in all probability a deposit of sulphate of potash. We say in all probability, because it is clear that if the potash in question is largely adulterated with soda, or was altogether nothing else than carbonate of soda, as has occasionally happened, it is evident that no deposit of sulphate of potash would take place; and yet as it is necessary to the success of the operation that the liquor should contain an excess of this latter salt, a certain quantity of it previously reduced to fine powder must in that case be purposely added to the solution.



71. After the disengagement of gas has ceased, it is necessary to pour the dilute acid cautiously, and only drop by drop, until the neutralising point is correctly hit, which will be known as usual by testing with litmus-paper. But if, by accident, too much acid have been used, which is known by the reddening of the litmus-paper, the slight overdose may be neutralised by adding a small quantity of weak solution of potash.

72. As this reaction produces heat, it is neccesary to lower the liquor down to the temperature of the atmosphere, decant in a filter placed over the glass cylinder, and fill it up to the scratch 3000, by washing the residue on the filter with a saturated solution of sulphate of potash, exactly as described in § 63.

73. The glass cylinder being properly filled up to the scratch, remove the funnel, close the orifice of the glass cylinder with the palm of the hand, and shake the whole violently; holding the natrometer, which should be perfectly clean, by its upper extremity, slowly immerse it in the solution. If the potash under examination be pure, the pink scale will indicate the degree of temperature at which the experiment has been made, taking the under line as the true level of the liquid; but if, on the contrary, it contains soda, the pink scale of temperatures will indicate a few degrees more than the real temperature, and this *surplus* number of degrees, being compared with those of the soda scale contiguous to it, on the opposite side, will express the per-centage of soda present in the sample.

74. For example:—Suppose the experiment to have been made at + 12° Centigrade and to have given a solution marking 25° on the pink scale of temperatures of the natrometer, that is 13° more than the real temperature;—looking therefore at number 13 on the pink scale of temperature, it will be seen that the number exactly opposite on the soda scale, and corresponding to it, is 4, which indicates that the sample of potash examined contains 4 per cent. of soda.

It is important to bear in mind that all commercial potashes contain naturally a small quantity of soda, which quantity, in certain varieties, may even be considerable: it is only when the proportion of soda is more considerable than that which is naturally contained *in the species* of potash submitted to analysis, that it should be considered as fradulently added. The following Table, published by M. Pesier, shows the average composition of the principal varieties of potash found in commerce, when in an unadulterated state.

Average Composition of Potashes.

	Tuscan Potash.	Russian Potash.	American Potash.	Pearlash.	Potash of the Vosges.	Potashes obtained in the Laboratory by calcining. A Mixture of pure Molasses. * In the impossibility of estimating exactly the loss by calcination, and the quantity of oxide of potassium in the caustic state (hydrate of potash), we have reduced the potash to the state of carbonate, to make comparison more easy.

Digitized by Google

75. *The alkalimetrical assay of soda* is performed exactly in the same manner as that of potash—that is to say: From a fair average sample of the soda to be examined, take 1000 grains' weight, (or less if that quantity cannot be spared,) and boil it five or six minutes in about eight fluid ounces of water, filter in order to separate the insoluble portion, and wash the residue on the filter with boiling water until it no longer drops from the filter with an alkaline reaction, and the bulk of the filtered liquid and the washings received in a graduated glass cylinder form 10,000 grains' measure. Should the water which may have been required to wash the residue have increased the bulk of the solution beyond that quantity, it should be evaporated to reduce it to the bulk mentioned.

76. This being done, 1000 water-grains' measure—that is to say, $\frac{1}{10}$th part of the aqueous solution of the soda ash above mentioned (§ 75)—are transferred to the glass beaker or vessel in which the saturation is intended to take place, it is tinged distinctly blue with tincture of litmus, and the operation is performed in the same manner and with the same precautions as for potash, the glass beaker containing the blue alkaline solution being placed upon a sheet of white paper, or a slab of white porcelain, the better to observe the change of colour which takes place when the saturating point is approaching.

77. Having put into a glass beaker the 1000 grains' measure of the aqueous solution of soda ash to be examined (§ 75), and if the *test sulphuric acid for soda*, described before (§§ 23-27) the alkalimeter, *fig.* 23, 24, or 25, should be filled with that test acid up to the point marked 0° (taking the under line of the liquid as the true level), and poured therefrom with the precaution already indicated, stirring briskly, at the same time, the liquid in the beaker. As is the case with the alkalimetrical assay of potash, the carbonic acid expelled by the test acid reacting upon the as yet undecomposed portion of the soda ash, converts it into bicarbonate of soda, so that at first no effervescence is produced; but as soon as half the quantity of the soda in the solution is saturated, a brisk effervescence takes place. At first, therefore, the operator may pour at once, without fear, a pretty large quantity of the test acid into the alkaline solution, but as soon as this effervescence makes its appearance he should proceed with increased precaution gradually as the saturating point is approached. The *modus operandi* is, in fact, precisely as already detailed for the assay of potash, precisely the same kind and amount of care is requisite, and the assay is known to be terminated when the streaks made upon the litmus-paper with the stirring rod remain distinctly and permanently of a pink colour.

78. After saturation, and after having allowed the sides of the alkalimeter to drain, the number of divisions at which the test acid stands in the alkalimeter indicate at once the per-centage of the soda assayed, since, as we said, each division of this particular test acid represents one grain of pure soda. If, therefore, the test acid stands at 52 in the alkalimeter, then the soda assayed contained 52 per cent. of real soda. See, besides, the observations of § 48 and following, and also § 81.

79. If, instead of the special test acid for soda just alluded to, the operator employs that which has a specific gravity of 1·032, and 100 alkalimetrical divisions of which saturate one equivalent of each base, the *modus operandi* is the same—that is to say, the alkalimeter is filled with it up to 0°, and it is poured therefrom carefully into the alkaline solution; but as the equivalent of soda is 31, and 100 alkalimetrical divisions of the test sulphuric acid now employed are capable of saturating only that quantity of soda, it is clear that with the soda ash taken as an example in the preceding case, and containing 52 per cent. of real soda, the operator will have to refil his alkalimeter with the same test acid, and that a certain number of divisions of this second filling will have to be employed to perfect the saturation. In this instance the operator will find that nearly 68 divisions more, altogether 168 divisions (correctly, 167°·74) have been required to effect the saturation.

80. If, instead of the special test sulphuric acid for soda (§§ 23-27), or the test sulphuric acid for potash, soda, and other bases (§§ 31-34), the operator uses the potash and soda alkalimeter (§§ 28-35), the method is always the same (§§ 74, 75)—that is to say, the aqueous solution of the soda ash is poured into the glass beaker, the difference being merely, that instead of the alkalimeter being quite filled up with the test sulphuric acid, which, in the present instance, has a specific gravity of 1·268 (§ 29), the said test acid is poured into the alkalimeter only up to the point marked "*soda*" (taking the under-line of the liquid as the true level), and the remaining divisions of the alkalimeter are carefully filled up with water. The mouth of the tube should then be thoroughly closed with the thumb of the left hand, and the whole violently shaken until perfectly mixed, taking great care, of course, not to squirt any of the acid out of the tube, which evidently would cause an amount of error proportionate to the quantity of the test acid which would have thus been lost. The acid should then be poured from the alkalimeter with the usual precaution

Digitized by Google

(§ 76) into the glass beaker containing the aqueous solution of the soda ash under examination, until complete neutralisation is attained, stirring briskly all the time, or after each addition of the test acid. The neutralisation point being hit, the sides of the alkalimeter are allowed to drain, and the operator then reads off the number of divisions employed, which number indicates the per-centage of real soda contained in the sample assayed. Thus, if the sample operated upon be the same as that alluded to before, the number of divisions employed being 52 would indicate 52 per cent. of real soda.

81. If the operator wishes to estimate the amount of soda in the sample as *carbonate of soda*, he should fill the alkalimeter with the test acid in question (specific gravity 1·268) up to the point marked *carbonate of soda*, and fill the remaining divisions with water, shake the whole well, and proceed with the neutralisation of the aqueous solution of the sample in the glass beaker as just described. Supposing, as before, that the sample in question contains 52 per cent. of real soda, it will now be found that the number of divisions employed altogether to saturate the sample completely are very nearly 89, for 52 of caustic soda correspond to 88·90 of the carbonate of that alkali.

82. If the soda ash is very poor, instead of operating upon 1000 water-grains' measure, or one-tenth part of the whole solution (= 100 grains' weight of the soda ash, §§ 76–77), it is advisable to take three or four thousand water-grains' measure of the alkaline solution, and to divide, by three or four, the result obtained by saturation. Suppose, for example, that the quantity of real soda found is 46; this, if only 1000 grains' measure had been taken, would, of course, indicate 46 per cent.; but as 4000 water-grains' measure of solution have been taken instead, that number 46 must, accordingly, be divided by 4, which gives 11½ per cent. only of real soda contained in the sample under examination.

83. The soda ash of commerce contains generally a per-centage of insoluble substances, which are removed by filtering, as we said, and a greater or less quantity of chloride of sodium (common salt) and of sulphate of soda, which, however, do not in the slightest degree interfere with the accuracy of the result. But there is a source of error resulting from the presence in the soda ash of sulphuret of calcium, of sulphite, and sometimes also, though more rarely, of hyposulphite, of soda. When sulphuret of calcium is present in the ash, on heating the latter by hot water, a double decomposition takes place, the sulphuret of calcium, reacting upon the carbonate of soda, forms sulphuret of sodium and carbonate of lime. Now sulphuret of sodium saturates the test acid just as carbonate of soda; but as it has no commercial value, it is clear that if the ash contains a quantity of the useless sulphuret at all considerable, a very serious damage may be sustained by the purchaser if the per-centage of that substance present in the ash be taken account of as being soda. Sulphite of soda is produced from the oxidisation of this sulphuret of sodium, and is objectionable inasmuch that when the test acid is added slowly to the aqueous solution of the ash, the effect is to convert the sulphite into bisulphite of soda, before any evolution of sulphurous acid, and consequently before the pink reaction on litmus-paper is produced.

84. In order to obviate the inaccuracies resulting from the neutralisation of a portion of the test acid by these substances, it is necessary to convert them into sulphates of soda, which is easily done by calcining a quantity of the sample with five or six per cent. of chlorate of potash, as recommended by Gay-Lussac and Welter. The operator, therefore, should intimately mix 50 or 60 grains' weight of pulverised chlorate of potash with 1000 grains of the pulverised sample, and fuse the mixture in a platinum crucible, for which purpose a blowpipe gas-furnace will be found exceedingly convenient. The fused mass should be washed, and the filtrate being received into a 10,000 water-grains' measure, and made up with water to occupy that bulk, may then be assayed in every respect as described before with one or other of the test acids mentioned.

85. When, however, the soda ash contains some hyposulphite of soda — which fortunately is seldom the case, for this salt is very difficultly produced in presence of a very large excess of alkali — it should not be calcined with chlorate of potash, because in that case one equivalent of hyposulphite becomes transformed *not into one equivalent of sulphate*, but, reacting upon one equivalent of carbonate of soda, expels its carbonic acid, and forms with the soda of the decomposed carbonate a *second equivalent* of sulphate of soda, each equivalent of hyposulphite becoming thus converted into two equivalents of sulphate, and therefore creating an error proportionate to the quantity of the hyposulphite present, each equivalent of which would thus destroy one equivalent of real and available alkali, and thus render the estimation of the sample inaccurate, and possibly to a very considerable extent.

86. When this is the case, it is therefore advisable, according to Messrs. Fordos and Gelis, to change the condition of the sulphurets, sulphites, and hyposulphites, by add-

Digitized by Google

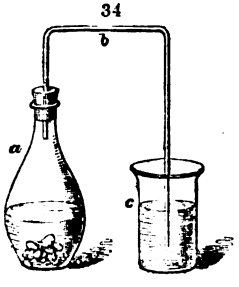
ing a little neutral chromate of potash to the alkaline solution, whence results sulphate of chromium, water, and a separation of sulphur, which will not affect the accuracy of the alkalimetrical process.

87. Whether the sample to be analysed contains any sulphuret, sulphite, or hyposulphite, is easily ascertained as follows:—If, on pouring sulphuric acid upon a portion of the sample of soda ash under examination, an odour of sulphuretted hydrogen —that is, an of odour rotten eggs—is evolved, or if a portion of the soda ash, being dissolved in water, and then filtered, produces a *black* precipitate (sulphuret of lead) when solution of acetate of lead is poured into it, then the sample contains a sulphuret.

88. And if, after adding to some dilute sulphuric acid as much bichromate of potash as is necessary to impart to it a distinct reddish-yellow tinge, and a certain quantity of the solution of the soda ash under examination being poured into it, but not in sufficient quantity to neutralise the acid, the reddish-yellow colour becomes green, it is a proof that the sample contains either sulphite or hyposulphite of soda, the green tinge being due to the transformation of the chromic acid into sesquioxyde of chromium.

89. And if, muriatic acid being poured into the *clear* solution of the soda ash, a turbidness supervenes after some time if left at rest, or at once if heat is applied, it is due to a deposit of sulphur, an odour of sulphurous acid being evolved, and hyposulphite of soda is probably present. We say probably, because if sulphurets and sulphites are present, the action of muriatic acid would decompose both, and liberate sulphuretted hydrogen and sulphurous acid; but as these two gases decompose each other, a turbidness due to a separation of sulphur is also formed; thus $2HS + SO^2 = 2HO + 2S$.

90. As we have already had occasion to remark, the soda ash of commerce frequently contains some, and occasionally a large quantity of caustic soda, the proportion of which it is at times important to determine. This may be done, according to Mr. Barreswill, by adding a solution of chloride of barium to the aqueous solution of the soda ash, by which the carbonate of soda is converted into carbonate of barytes, whilst the caustic soda, reacting upon the chloride of barium, liberates a quantity of caustic barytes proportionate to that of the caustic soda in the soda ash. After this addition of chloride of barium, the liquor is filtered in order to separate the precipitated carbonate of barytes produced, and which remains on the filter, on which it should be washed with pure water. A few lumps of chalk are then put into a Florence flask, *a*, and some muriatic acid being poured upon it, an effervescence due to a disengagement of carbonic acid is produced, the flask is then closed with a good cork, provided with a bent tube, *b*, reaching to the bottom of the vessel *c*, and the stream of carbonic acid produced is then passed through the liquor *c*, filtered from the carbonate of barytes above mentioned. The stream of carbonic acid produces a precipitate of carbonate of barytes, which should be also collected on a separate filter, washed, dried, and weighed. Each grain of this second precipitate of carbonate of barytes corresponds to 0·3157 of caustic soda.



91. As the soda ash of commerce almost invariably contains earthy carbonates, the sample operated upon should always be dissolved in hot water, and filtered in order to separate the carbonate of lime which otherwise would saturate a proportionate quantity of the test acid, and thus render the analysis worthless.

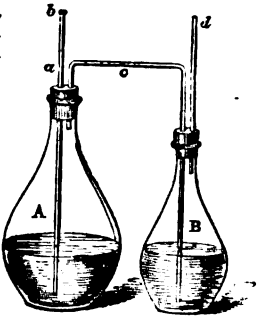
92. The quantity of water contained in either potash or soda ash is ascertained by heating a weighed quantity of the sample to redness in a covered platinum capsule or crucible. The loss after ignition indicates the proportion of water. If any caustic alkali is present, 1 equivalent, = 9 of water, is retained, which cannot be thus eliminated, but which may, of course, be determined by calculation after the proportion of caustic soda has been found, as shown before, each 31 grains of caustic soda containing 9 grains of water.

93. Besides the alkalimetrical processes which have been explained in the preceding pages, the proportion of available alkali contained in the sample may be estimated from the amount of carbonic acid which can be expelled by supersaturating the alkali with an acid. The determination of the value of alkalis from the quantity of carbonic acid thus evolved by the supersaturation of the carbonate acted upon has long been known. Dr. Ure, in the "Annals of Philosophy," for October, 1817, and then in his "Dictionary of Chemistry," 1821, and more recently in his pamphlet "Chemistry Simplified," described several instruments for analysing earthy and alkaline

Digitized by Google

carbonates, and for a description of which the reader is referred to the article on ACIDIMETRY. The ingenious little apparatus of Drs. Fresenius and Will for the same purpose, and to which we have already alluded in the same article, gives accurate results; but it should be observed that when the potash or soda of commerce contains any caustic alkali, or bicarbonate, or earthy carbonates, or sulphuret of alkali—which, as we have seen, is frequently, and, indeed, almost invariably, the case, the process is no longer applicable without first submitting the sample to several operations—which render this process troublesome and unsuited to unpractised hands. Thus, if caustic potash is present, the sample must be first mixed and triturated with its own weight of pure quartzose sand and about one-third of its weight of carbonate of ammonia. The mass is then moistened with aqueous ammonia, and then put into a small iron capsule and evaporated to dryness, so as to expel completely the ammonia and carbonate of ammonia. The mass is then treated by water, filtered, washed, and concentrated to a proper bulk by evaporation, transferred to the apparatus, and treated as will be seen presently. If the sample contains caustic soda, instead of one-third, at least half of its weight of carbonate of ammonia should be employed. But for the estimation of *pure* carbonates, Drs Fresenius and Will's method is both accurate and easy. The apparatus consists of two flasks, A and B; the first should have a capacity of from two to two ounces and a half; the second, or flask B, should be of a somewhat smaller size, and hold about one and a half or two ounces. Both should be provided with perfectly sound corks, each perforated with two holes, through which the tubes *a*, *c*, *d* are passing. The lower extremity of the tube *a* must be adjusted so as to reach nearly to the bottom of the flask A, and its upper extremity is closed by means of a small pellet of wax, *b*; *c* is a tube bent twice at right angles, one end of which merely protrudes through the cork into the flask A, but the other end reaches nearly to the bottom of the flask B. The tube *d* of the flask B merely protrudes through the cork into the flask.

35



95. The apparatus being so constructed, a certain quantity — 100 grains, for example — of the potash or soda ash under examination (and which may have been previously dried) is weighed and introduced into the flask A, and water is next poured into this flask to about one-third of its capacity Into the other flask, or flask B, concentrated ordinary sulphuric acid is poured, and the corks are firmly put in the flasks, which thus become connected, so as to form a twin-apparatus, which is then carried to a delicate balance, and accurately weighed. This done, the operator removes the apparatus from the balance, and applying his lips to the extremity of the tube *d*, sucks out a few air-bubbles, which, as the other tube, *a*, is closed by the wax pellet, rarefies the air in the flask A, and consequently causes the sulphuric acid of flask B to ascend a certain height (after the suction) into the tube *c*; and if, after a short time, the column of sulphuric acid maintains its height in the tube *c*, it is a proof that the apparatus is air-tight, and therefore as it should be. This being ascertained, suction is again applied to the extremity of the tube *d*, so that a portion of the sulphuric acid of the flask B ascends into the tube *c*, and presently falls into the flask A, the quantity which thus passes over being, of course, proportionate to the vacuum produced by the suction. As soon as the acid thus falls in the water containing the alkaline carbonate in the flask A, an effervescence is immediately produced, and as the carbonic acid disengaged must, in order to escape, pass, by the tube *c*, through the concentrated sulphuric acid of the flask B, it is thereby completely dried before it can finally make its exit through the tube *d*. The effervescence having subsided, suction is again applied to the tube *d*, in order to cause a fresh quantity of sulphuric acid to flow over into the flask A, as before; and so on, till the last portion of sulphuric acid sucked over produces no effervescence, which indicates, of course, that all the carbonate is decomposed, and that, consequently, the operation is at an end. A powerful suction is now applied to the tube *d*, in order to cause a tolerably large quantity of sulphuric acid, but not all, to flow into the flask A, which thus becomes very hot, from the combination of the concentrated acid with the water, so that the carbonic acid is thereby thoroughly expelled from the solution. The little wax pellet which served as a stopper is now removed from the tube *d*, and suction applied for some time, in order to sweep the flasks with atmospheric air, and thus displace all the carbonic acid in the apparatus, which is allowed to become *quite cold*, and weighed again, together with the wax pellet, the difference between the first and the second weighing—that is to say, the loss—indicating the quantity of carbonic acid which was contained in the carbonate, which has escaped, and from which, of

Digitized by Google

course, the quantity of the carbonated alkali acted upon may be calculated. Suppose in effect, that the loss is 19 grains : taking the

Equivalent of soda	- - - - - - -	= 31
do carbonic acid	- - - - - - -	= 22
1 equivalent of carbonate of soda	- -	= 53,

it is clear that the 19 grains of carbonic acid which have been expelled represent 45·77 grains of carbonate of soda, or, in other words, 100 grains of soda ash operated upon contained 45·77 of real carbonate of soda, thus :—

$$CO^2 \quad NaO^1CO^2 \quad CO^2 \qquad NaO^1CO^2$$
$$22 \; : \; 53 \; :: \; 19 \; : \; x \; = \; 45{\cdot}77$$

96. As the soda ash of commerce always contains earthy carbonates, and very frequently sulphurets, sulphites, and occasionally hyposulphites, instead of putting the 100 grains to be operated upon directly into the flask A, it is absolutely necessary first to dissolve them in boiling water, to filter the solution, and to wash the precipitate which may be left on the filter with boiling water. The solution and the washings being mixed together, should then be reduced by evaporation to a proper volume for introduction into the flask A, and the process is then carried on as described. If sulphuret, sulphites, or hyposulphites are present, the ash should be treated exactly as mentioned in §§ 83–91, previous to pouring the solution into the flask A, since otherwise the sulphuretted hydrogen and sulphurous acid, which would be disengaged along with the carbonic acid, would apparently augment the proportion of the latter, and render the result quite erroneous.

97. The balance used for this mode of analysis should be capable of indicating small weights when heavily laden.—A. N.

ALKALINE EARTHS—Barytes, Lime, and Strontia. These earths are so called to distinguish them from the earths Magnesia and Alumina. They are soluble in water, but to a much less extent than the alkalies. Their solutions impart a brown colour to tumeric paper, and neutralise acids. They are, however, distinguished from the alkalies, by their combination with carbonic acid being nearly insoluble in water.

ALKANET (*Orcanette*, Fr.; *Orkanet*, Germ.). *Anchusa tinctoria.* A species of bugloss, or boragewort, cultivated in the neighbourhood of Montpellier and in the Levant. It is sometimes called the bugloss of Languedoc, or the dyer's bugloss. The anchusa is a rough plant, with downy and spear-shaped leaves, and clusters of small purple or reddish flowers, the stamens of which are shorter than the corolla. It affords a fine red colour to alcohol and oils, but a dirty red to water. Its principal use is for colouring ointments, oils, and *pommades.* The spirituous tincture gives to white marble a beautiful deep stain ; but, usually, wax is coloured with the anchusa, and then applied to the surface of warm marble. It stains it flesh-colour, and the stain sinks deep into the stone.

Alkanet root was analysed by Dr. John, who found the constituents to be a *peculiar colouring* matter (*pseudo-alkanium*), 5·50; extractive, 1·00; gum, 6·25; matters extracted by caustic potash, 65 00; woody fibre, 18·00.

The colouring matter resides in the cortical part of the root, and was regarded by Pelletier as a kind of fatty acid (*anchusic acid*); but it is now usually considered to be a resinoid (*anchusine*), whose composition is $C^{35}\,H^{36}\,O^3$ This root is sometimes termed the spurious *alkanet root* (*radix alkannæ spuriæ*), to distinguish it from the Al-kenna.

AL-KENNA, or AL-HENNA, is the name of the roots and leaves of *Lawsonia inermis*, which have been long employed in the East to dye the nails, teeth, hair, garments, &c. The leaves, ground and mixed with a little limewater, serve for dyeing the tails of horses in Persia and Turkey.

It is the same as the herb *Henna* frequently referred to by the Oriental poets. The powder of the leaves, being wet, forms a paste, which is bound on the nails for a night, and the colour thus given will last for several weeks.

This plant is distinguished as the true alkanet root (*radix alkennæ vera*).

ALLIGATION. An arithmetical formula, useful on many occasions for ascertaining the proportion of constituents in a mixture, when they have undergone no change of volume by chemical action, or for finding the price or value of compounds consisting of ingredients of different values. Thus, if a quantity of sugar worth 8*d.* the pound, and another quantity worth 10*d.*, are mixed, the question to be solved by alligation is, what is the value of the mixture by the pound ? Alligation is of two kinds—*medial* and *alternate* ; *medial*, when the rate of mixture is sought from the rates and quantities of the simples ; *alternate*, when the quantities of the simples are sought from the rates of the simples and the rate of the mixture.—*Webster.*

Digitized by Google

ALLIOLE. *Alliole* is obtained by distilling crude naphtha, and collecting all that leaves the still in the first distillation before the boiling temperature reaches 194°F.; and on the second distillation, all below 176°F. It boils, when nearly free from *benzole*, at a temperature of from 140° to 158° F., and possesses an alliaceous odour somewhat resembling sulphide of carbon.

ALLIUM SATIVUM. See GARLIC.

ALLOPHANE—from ἄλλος *other*, and φαίνω *to appear*, in allusion to the change of appearance which this mineral undergoes before the blowpipe flame. This mineral, which is essentially silica 24·22, alumina 40·39, and water 35·39, is generally found lining small cavities, and in veins in marl or chalk. Allophanes have been found containing from 14 to 19 per cent. of oxide of copper.

ALLOTROPY. *Allotropic Condition.* A name introduced by Berzelius to signify *another form* of the same substance, derived from ἄλλος, another, and τρόπος, habit. Carbon, for example, exists as the diamond, a brilliant gem, with difficulty combustible; as graphite, a dark, heavy, opaque mass, often crystalline, also of great infusibility; and as charcoal, a dark porous body, which burns with facility.

Sulphur, when melted, is at 230° F. perfectly liquid. Being heated to 430° F., it becomes thick and so tenacious that it can scarcely be poured out of the vessel in which it is melted. When heated to 480° it again becomes liquid, and continues so until it boils. These examples are sufficient to explain the meaning of this term. An extensive series of bodies appears to assume similar allotropic modifications. The probability is that, with the advance of physical and chemical science, many of the substances now supposed to be elementary will be proved to be but allotropic states of some one form of matter. Deville has already shown that silicon and boron exist, like the diamond, in three allotropic states—one of the conditions of boron being much harder than the diamond. See ISOMERISM.

ALLOY. (*Alliage*, Fr.; *Legirung*, Germ.) From the French *allier*, to unite or mix; or the Latin *alligo*, to bind. This term formerly signified mixing some baser metal with gold and silver, and this meaning is still preserved in reference to coinage; but, in chemistry, it now means any compound of any two or more metals whatever. Thus, bronze is an alloy of copper and tin; brass, an alloy of copper and zinc; and type metal, an alloy of lead and antimony. All the alloys possess metallic lustre, even when cut or broken to pieces; they are opaque; are excellent conductors of heat and electricity; are frequently susceptible of crystallising; are more or less ductile, malleable, elastic, and sonorous. An alloy which consists of metals differently fusible is usually malleable when cold, and brittle when hot, as is exemplified with brass and gong metal.

Many alloys consist of definite or equivalent proportions of the simple component metals, though some alloys seem to form in any proportion, like combinations of salt or sugar with water. It is probable that peculiar properties belong to the equivalent or atomic ratio, as is exemplified in the superior quality of brass made in that proportion.

The experiments of Crookewitt upon amalgams appear to prove that the combination of metals in alloys obeys some laws of a similar character to those which prevail between combining bodies in solution; *i.e.* that a true combining proportion existed.

By amalgamation and straining through chamois leather, he obtained crystalline metallic compounds of gold, bismuth, lead, and cadmium, with mercury, which appeared to exist in true definite proportions. With potassium he obtained two amalgams, KHg^{20} and KHg^{16}. With silver, by bringing mercury in contact with a solution of nitrate of silver, according to the quantity of mercury employed, he obtained such amalgams as Ag^3Hg^{16}, $AgHg^2$, $AgHg^3$, $AgHg^4$.

Beyond those there are many experiments which appear to prove that alloys are true chemical compounds; but, at the same time, it is highly probable that the true chemical alloy is very often *dissolved* (mechanically disseminated) in that metal which is largely in excess.

Some years since, the editor carried out an extensive series of experiments in the laboratory of the Museum of Practical Geology, with the view of obtaining a good alloy for soldiers' medals, and the results confirmed his views respecting the laws of definite, proportional combination among the metals. Many of those alloys were struck at the Mint, and yielded beautiful impressions; but there were many objections urged against the use of any alloy for a medal of honour.

One metal does not alloy indifferently with every other metal, but it is governed in this respect by peculiar affinities; thus, silver will hardly unite with iron, but it combines readily with gold, copper, and lead. In comparing the alloys with their constituent metals, the following differences may be noted. In general, the ductility of the alloy is less than that of the separate metals, and sometimes in a very remark-

Digitized by Google

able degree; on the contrary, the alloy is usually harder than the mean hardness of its constituents. The mercurial alloys or amalgams are, perhaps, exceptions to this rule.

The specific gravity is rarely the mean between that of each of its constituents, but is sometimes greater and sometimes less; indicating, in the former case, a closer cohesion; and, in the latter, a recedure, of the particles from each other in the act of their union. The alloys of the following metals have been examined by Crookewitt, and he has given their specific gravities as in the following Table; the specific gravity of the unalloyed metals being—

Copper - -	8·794	Zinc - -	6·860
Tin - - -	7·305	Lead - -	11·354

That of the alloys was—

$Cu^2 Sn^5$ - -	7·652	Cu Pb - -	10·375
Cu Sn - -	8·072	$Sn Zn^3$ - -	7·096
$Cu^2 Sn$ - -	8·512	Sn Zn - -	7·115
$Cu^3 Zn^5$ - -	7·939	$Sn^3 Zn$ - -	7·235
$Cu^3 Zn^2$ - -	8·224	$Sn Pb^2$ - -	9·965
$Cu^2 Zn$ - -	8·392	Sn Pb - -	9·394
$Cu^2 Pb^3$ - -	10 753	$Sn^3 Pb$ - -	9·025

The following Tables of binary alloys exhibit this circumstance in experimental detail:—

Alloys having a density greater than the mean of their constituents.	Alloys having a density less than the mean of their constituents:
Gold and zinc	Gold and silver
Gold and tin	Gold and iron
Gold and bismuth	Gold and lead
Gold and antimony	Gold and copper
Gold and cobalt	Gold and iridium
Silver and zinc	Gold and nickel
Silver and lead	Silver and copper
Silver and tin	Iron and bismuth
Silver and bismuth	Iron and antimony
Silver and antimony	Iron and lead
Copper and zinc	Tin and lead
Copper and tin	Tin and palladium
Copper and palladium	Tin and antimony
Copper and bismuth	Nickel and arsenic
Lead and antimony	Zinc and antimony
Platinum and molybdenum	
Palladium and bismuth	

There are many points of great physical as well as chemical interest in connection with alloys, which require a closer study than they have yet received. There are some striking facts, brought forward by M. Wertheim, deduced from experiments carried on upon fifty-four binary alloys and nine ternary alloys of simple and known composition, which will be found in the "Journal of the French Institute," to which the reader desiring information on this point is referred.

It is hardly possible to infer the melting point of an alloy from that of each of its constituent metals; but, in general, the fusibility is increased by mutual affinity in their state of combination. Of this a remarkable instance is afforded in the fusible metal consisting of 8 parts of bismuth, 5 of lead, and 3 of tin, which melts at the heat of boiling water, or 212° F., though the melting point deduced from the mean of its components should be 514° F. This alloy may be rendered still more fusible by adding a little mercury to it, when it forms an excellent material for anatomical injections. See FUSIBLE METAL.

On the Melting Point of Certain Alloys.

	Centrigrade Thermometer.		Centrigrade Thermometer.

The colours of alloys do not depend in any considerable degree upon those of the separate metals; thus, the colour of copper, instead of being rendered paler by a large addition of zinc, is thereby converted into a rich-looking metal, brass.

By means of alloys, we multiply, as it were, the numbers of useful metals, and sometimes give usefulness to such as are separately of little value. Since these compounds can be formed only by fusion, and that many metals are apt to oxidise readily at their melting temperature, proper precautions must be taken in making alloys to prevent this occurrence. Thus, in combining tin and lead, resin or grease is usually put on the surface of the melting metals, the carbon produced by the decomposition of which protects them, in most cases, sufficiently from oxidisement. When we wish to combine tin with iron, as in the tinning of cast-iron tea kettles, we rub sal ammoniac upon the surfaces of the hot metals in contact with each other, and thus exclude the atmospheric oxygen by means of its fumes. When there is a notable difference in the specific gravities of the metals which we wish to combine, we often find great difficulties in obtaining homogeneous alloys; for each metal may tend to assume the level due to its density, as is remarkably exemplified in alloys of gold and silver made without adequate stirring of the melting metals. If the mass be large and slow of cooling, after it is cast in an upright cylindrical form, the metals sometimes separate, to a certain degree, in the order of their densities. Thus, in casting large bells and cannon with copper alloys, the bottom of the casting is apt to contain too much copper and the top too much tin, unless very dexterous manipulation in mixing the fused materials has been employed immediately before the pouring out of the melted mass. When such inequalities are observed, the objects are broken and re-melted, after which they form a much more homogeneous alloy. This artifice of a double melting is often had recourse to, and especially in casting the alloys for the specula of telescopes.

When we wish to alloy three or more metals, we often experience difficulties, either because one of the metals is more oxidable, or denser, or more fusible, than the others, or because there is no direct affinity between two of the metals. In the latter predicament, we shall succeed better by combining the three metals first in pairs, for example, and then melting the two pairs together. Thus, it is difficult to unite iron with bronze directly; but if, instead of iron, we use tin plate, we shall immediately succeed, and the bronze, in this manner, acquires valuable qualities from the iron. Thus, also, to render brass better adapted for some purposes, a small quantity of lead is sometimes added to it, but this cannot be done directly with advantage; it is better to melt the lead first along with the zinc, and then to add this alloy to the melting copper, or the copper to that alloy, and fuse them together.

One of the alloys most useful to the arts is brass; it is more ductile and less easily oxidised than even its copper constituent, notwithstanding the opposite nature of the zinc. (See BRASS.) This alloy may exist in many different proportions, under which it has different names, as tombac, similor, pinchbeck, &c. Copper and tin form compounds of remarkable utility, known under the name of *hard brass*, for the bushes, steps, and bearings of the axles, arbours, and spindles in machinery; and of *bronze*, *bell-metal*, &c. (See BRONZE, &c.) Gold and silver, in their pure state, are too soft and flexible to form either vessels or coins of sufficient strength and durability; but when alloyed with a little copper, they acquire the requisite hardness and stiffness for these and other purposes. Aluminium has been found by Dr. Percy to possess the same hardening property.

When we have occasion to unite several pieces of the same or of different metals, we employ the process called *soldering*, which consists in fixing together the surfaces by means of an interposed alloy, which must be necessarily more fusible than the metal or metals to be joined. That alloy must also consist of metals which possess a strong affinity for the substances to be soldered together. Hence each metal would seem to require a particular kind of solder, which is, to a certain extent, true. Thus, the solder for gold trinkets and plate is an alloy of gold and silver, or gold and copper; that for silver trinkets is an alloy of silver and copper; that for copper is either fine tin, for pieces that must not be exposed to the fire, or a brass alloy called hard solder, of which the zinc forms a considerable proportion. The solder of lead and tinplate is an alloy of lead and tin, and that of tin is the same alloy with a little bismuth. Tinning, gilding, and silvering may also be reckoned a species of alloys, since the tin, gold, and silver are superficially united in these cases to other metals.

Metallic alloys possess usually more tenacity than could be inferred from their constituents; thus, an alloy of 12 parts of lead with 1 of zinc has a tenacity double that of zinc.

The cohesive force of alloys is well shown in the following Table, in which the results are mostly those obtained by Muschenbroek.*

Metallic alloys are much more easily oxidised than the separate metals, a phenomenon which may be ascribed to the increased affinity for oxygen which results from the tendency of the one of the oxides to combine with the other. An alloy of tin and lead heated to redness takes fire, and continues to burn for some time like a piece of bad turf.

Every alloy is, in reference to the arts and manufactures, a new metal, on account of its chemical and physical properties. A vast field here remains to be explored. Not above 60 alloys have been studied by the chemists out of many hundred which may be made; and of these but few have yet been practically employed. Very slight modifications often constitute valuable improvements upon metallic bodies. Thus, the brass most esteemed by turners at the lathe contains from 2 to 3 per cent. of lead; but such brass does not work well under the hammer; and, reciprocally, the brass which is best under the hammer is too tough for turning.

M. Chaudet has made some experiments on the means of detecting the metals of alloys by the cupelling furnace, and they promise useful applications. The testing depends upon the appearance exhibited by the metals and their alloys when heated on a cupel. The following were Chaudet's results: —

Metals.—Pure tin, when heated this way, fuses, becomes of a greyish-black colour, fumes a little, exhibits incandescent points on its surface, and leaves an oxide which,

Digitized by Google

when withdrawn from the fire, is at first lemon-yellow, but, when cold, white. Antimony melts, preserves its brilliancy, fumes, and leaves the vessel coloured lemon-yellow when hot, but colourless when cold, except a few spots of a rose tint. Zinc burns brilliantly, forming a cone of oxide; and the oxide, much increased in volume, is, when hot, greenish, but, when cold, perfectly white. Bismuth fumes, becomes covered with a coat of melted oxide, part of which sublimes, and the rest enters the pores of the cupel; when cold, the cupel is of a fine yellow colour, with spots of a greenish hue. Lead resembles bismuth very much; the cold cupel is of a lemon-yellow colour. Copper melts, and becomes covered with a coat of black oxide; sometimes spots of a rose tint remain on the cupel.

ALLOYS.—Tin 75, antimony 25, melt, become covered with a coat of black oxide, have very few incandescent points; when cold, the oxide is nearly black, in consequence of the action of the antimony; a $\frac{1}{200}$th part of antimony may be ascertained, in this way, in the alloy. An alloy of antimony containing tin leaves oxide of tin in the cupel: a $\frac{1}{100}$th part of tin may be thus detected. An alloy of tin and zinc gives an oxide which, whilst hot, is of a green tint, and resembles philosophers' wool in appearance. An alloy containing 99 tin 1 zinc did not present the incandescent points of pure tin, and gave an oxide of greenish tint when cold. Tin 95, bismuth 5 parts, gave an oxide of a grey colour. Tin and lead give an oxide of a rusty brown colour. An alloy of lead and tin, containing only 1 per cent. of the latter metal, when heated, does not expose a clean surface, like lead, but is covered at times with oxide of tin. Tin 75 and copper 25 gave a black oxide: if the heat be much elevated, the under part of the oxide is white, which is oxide of tin; the upper part is black, being the oxide of copper, and the cupel becomes of a rose colour. If the tin be impure from iron, the oxide produced by it is marked with spots of a rust colour.

The degree of affinity between metals may be in some measure estimated by the greater or less facility with which, when of different degrees of fusibility or volatility, they unite, or with which they can, after union, be separated by heat. The greater or less tendency to separate into differently proportioned alloys, by long-continued fusion, may also give some information upon this subject. Mr. Hatchett remarked, in his elaborate researches on metallic alloys, that gold made standard with the usual precautions, by silver, copper, lead, antimony, &c., and then cast, after long fusion, into vertical bars, was by no means an uniform compound; but that the top of the bar, corresponding to the metal at the bottom of the crucible, contained the larger proportion of gold. Hence, for a more thorough combination, two red-hot crucibles should be employed, and the liquefied metals should be alternately poured from the one into the other. To prevent unnecessary oxidisation from the air, the crucibles should contain, besides the metal, a mixture of common salt and pounded charcoal. The metallic alloy should also be occasionally stirred up with a rod of earthenware.

When there is a strong affinity between the two metals, their alloy is generally denser than the mean, and *vice versâ*. This is exemplified, as previously shown, in the alloys of copper with zinc and tin, on the one hand, and with copper and lead on the other. When one of the metals, however, is added in excess, there result an atomic compound and an indefinite combination, as would appear from Muschenbroek's experiments. Thus,

1	of lead with	4	of silver give a density of	10·480
1	do	2	do	11·032
1	do	3	do	10·831

The proportion of the constituents is on this principle estimated in France by the *test of the ball* applied to pewter; in which the weight of the alloyed ball is compared with that of a ball of pure tin or standard pewter cast in the same mould. Alloys possess the elasticity belonging to the mean of their constituents, and also the specific caloric.

According to M. Rudberg, while lead solidifies at 325° C., and tin at 228°, their atomic alloy solidifies at 187°, which he calls the fixed point, for a compound $Pb\,Sn^3$.

An alloy too slowly cooled is often apt to favour the crystallisation of one or more of its components, and thus to render it brittle; and hence an iron mould is preferable to one of sand when there is danger of such a result.

It is not a matter of indifference in what order the metals are melted together in making an alloy. Thus, if we combine 90 parts of tin and 10 of copper, and to this alloy add 10 of antimony; or if we combine 10 parts of antimony with 10 of copper, and add to that alloy 90 parts of tin, we shall have two alloys chemically the same; and still it will be easy to discover that, in other respects — fusibility, tenacity, &c. — they totally differ. Whence this result? Obviously from the nature of their combination, dependent upon the order pursued in the preparation, and which continues after the mixture. In the alloys of lead and antimony also, if the heat be raised in combining

Digitized by Google

the two metals together much above their fusing points, the alloy becomes harsh and brittle; probably because some alloy formed at that high temperature is not soluble in the mass.

In common cases the specific gravity affords a good criterion whereby to judge of the proportion of two metals in an alloy. But a very fallacious rule has been given in some respectable works for computing the specific gravity that should result from the alloying of given quantities of two metals of known densities, supposing no chemical condensation or expansion of volume to take place. Thus, it has been taught, that if gold and copper be united in equal weights, the computed specific gravity is merely the arithmetical mean between the numbers denoting the two specific gravities. Whereas, the specific gravity of any alloy must be computed by dividing the sum of the two weights by the sum of the two volumes, compared, for conveniency sake, to water reckoned unity. Or, in another form, the rule may be stated thus:—Multiply the sum of the weights into the products of the two specific-gravity numbers for a numerator; and multiply each specific-gravity number into the weight of the other body, and add the two products together for a denominator. The quotient obtained by dividing the said numerator by the denominator, is the truly computed mean specific gravity of the alloy. On comparing with that density the density found by experiment, we shall see whether expansion or condensation of volume has attended the metallic combination. Gold having a specific gravity of 19·36, and copper of 8·87, when they are alloyed in equal weights, give, by the fallacious rule of the arithmetical mean of the densities $\frac{19{\cdot}36 + 8{\cdot}87}{2} = 14{\cdot}11$; whereas the rightly computed density is only 12·16. It is evident that, on comparing the first result with experiment, we should be led to infer that there had been a prodigious condensation of volume, though expansion has actually taken place. Let W, w be the two weights; P, p the two specific gravities, then M, the mean specific gravity, is given by the formula

$$M = \frac{(W+w)\,Pp}{Pw + pW} \therefore 2\,\Delta = -\frac{(P-p)^2}{P+p} = \text{twice}$$

the error of the arithmetical mean; which is therefore always in excess.

Alloys of a somewhat complex character are made by Mr. Alexander Parkes, of Birmingham, of a white or pale colour, by melting together 33¼ lbs. of foreign zinc, 64 of tin, 1½ of iron, and 3 of copper; or 50 zinc, 48 tin, 1 iron, and 3 copper; or any intermediate proportion of zinc and copper may be used. The iron and copper are first melted together in a crucible, the tin is next introduced, in such quantities at a time as not to solidify the iron and copper; the zinc is added lastly, and the whole mixed by stirring. The flux recommended for this alloy is, 1 part of lime, 1 part of Cumberland iron ore, and 3 parts of sal ammoniac.

Another of his alloys is composed of 66 lbs. of foreign zinc, 33¼ tin, 3¼ antimony; or 70¾ zinc, 19¼ tin, and 2¾ antimony; or any intermediate proportions, and with or without arsenic. He uses black flux. When to be applied to the sheathing of ships, from 8 to 16 oz. of metallic arsenic are added to every 100 lbs. of alloy. A third class of alloys consists of equal parts of iron and nickel; the copper is next added, and lastly the zinc, or the copper and zinc, may be added as an alloy. 100 lbs. may consist of 45¼ lbs. of iron and nickel (*partes æquales*), and 10¼ lbs. of foreign zinc; or 30¾ lbs. of alloy of iron and nickel (*p. æ.*), 46 copper, and 26¼ zinc; or any intermediate proportions of zinc and copper. He uses also an alloy of 60 lbs. of copper, 20 of zinc, and 20 of silver; or 60 copper, 10 nickel, 10 silver, and 20 zinc; the copper and nickel being first fused together. His fifth alloy is called by him a non-conductor of heat! It is made of 25 nickel, 25 iron, and 50 copper; or 15 nickel, 25 iron, and 60 copper; the last being added after the fusion of the others.

It may prove convenient to give a general statement of the more striking peculiarities of the important alloys. More detailed information will be found under the heads of the respective metals.

Gold and Silver Alloys.— The British standard for gold coin is 22 parts pure gold and 2 parts alloy, and for silver, 222 parts pure silver to 18 parts of alloy.

The alloy for the gold is an indefinite proportion of silver and copper: some coin has a dark red-colour from the alloy being chiefly copper; the lighter the colour a larger portion of silver is indicated, sometimes even (when no copper is present) it approaches to a greenish tinge, but the proportion of pure gold is the same in either case.

The alloy for silver coinage is always copper; and a very pure quality of this metal is used for alloying, both for the gold and silver coinage, as almost any other

Digitized by Google

metal being present, even in very small quantities, would make the metals unfit for coinage, from rendering the gold, silver, and copper brittle, or not sufficiently malleable.

The standard for plate (silver) is the same as the coin, and requires the same quantity of copper, and carefully melting with two or three bits of charcoal on the surface while in fusion, to prevent the oxidation of the copper by heat and exposure to the atmosphere.

The gold standard for plate and jewellery varies, by a late act of Parliament, from the 22 carats pure, to 18, 12, and 9: the alloys are gold and silver, in various proportions according to the taste of the workmen; the colour of the articles manufactured depending, as with the coin, on the proportions; if no copper is used in qualities under 22 carats fine gold, the colour varies from a soft green to a greenish white, but a proportion of copper may be used so as to bring the colour to nearly that of 22 fine, 1 silver, and 1 copper.

Wire of either gold or silver may be drawn of any quality, but the ordinary wire for fine purposes, such as lace, contains from 5 to 9 pennyweights of copper in the pound of 240 pennyweights, to render it not so soft as it would be with pure silver.

Gold, silver, and copper may be mixed in any proportions without injury to the ductility, but no reliable scale of tenacity appears to have been constructed, although gold and silver in almost any proportions may be drawn to the very finest wire.

The alloys of silver and palladium may be made in any proportions; it has been found that even 3 per cent. of palladium prevents silver tarnishing so soon as without it; 10 per cent. very considerably protects the silver, and 30 per cent. of palladium will prevent the silver being affected by fumes of sulphuretted hydrogen unless very long exposed: the latter alloy has been found useful for dental purposes, and the alloy with less proportions—say 10 to 15 per cent.—has been used for graduated scales of mathematical instruments.

The alloy of platinum and silver is made for the same purposes as those of palladium, and, by proper care in fusion, are nearly equally useful, but the platinum does not seem to so perfectly combine with the silver as the palladium. Any proportion of palladium with gold injures the colour, and even 1 per cent. may be detected by sight, and 5 per cent. renders it a silver colour, while about 10 per cent. destroys it; but the ductility of the alloy is not much injured.

Gold leaf for gilding contains from 3 to 12 grains of alloy to the ounce. The gold used by respectable dentists is nearly pure, but necessarily contains about 6 grains of copper to the ounce troy, or $\frac{1}{40}$th part.

Antimony in the proportion of $\frac{1}{1920}$ quite destroys the ductility of gold.

Gold and platinum alloy forms a somewhat elastic metal. Hermstadt's imitation of gold consists of 16 parts of platinum, 7 parts of copper, and 1 of zinc, put in a crucible, covered with charcoal powder, and melted into a mass.—P. J.

Dentists' Alloy. For the ordinary purposes of mounting artificial teeth a peculiar metal is required. It must be sufficiently hard and tough, and it must not be liable to corrosion by either acid or acrid fluids. Experience has shown that an alloy of gold, silver, and copper most nearly meets all the required conditions. Dentists use 16-carat gold, which is $\frac{2}{3}$ fine gold and $\frac{1}{3}$ alloy, the alloy being always nearly equal portions of silver and copper, which is not, for these purposes, in the slightest degree injurious.—See AMALGAM.

COPPER ALLOYS.—Copper alloyed with zinc forms BRASS, and with tin we have BRONZE. (See those articles.) The best *Kingston's Metal* is an alloy of copper, tin, and mercury; it is much used for bearings. (See KINGSTON'S METAL.) The alloys of the ancients were usually either brasses or bronzes. The following analyses of ancient coins, &c., by Mr. John Arthur Phillips, are of great value.

It is not a little curious to find that some of the coins of high antiquity contain zinc, which does not appear to have been known as a metal before 1280 A.D., when Albertus Magnus speaks of zinc as a *semi-metal*, and calls the alloy of copper and zinc *golden marcasite*; or rather, perhaps, he means to apply that name to zinc, from its power of imparting a golden colour to copper. The probability is that calamine was known from the earliest times as a peculiar earth, although it was not thought to be an ore of zinc or of any other metal.—See "Watson's Chemical Essays."

Copper, when united with half its weight of lead, forms an inferior alloy, resembling gun-metal in colour, but is softer and cheaper. This alloy is called *pot-metal* and *cock-metal*, because it is used for large measures and in the manufacture of taps and cocks of all descriptions.

Sometimes a small quantity of zinc is added to pot-metal; but when this is considerable the copper seizes the zinc to form brass, and leaves the lead at liberty, a large portion of which separates on cooling. Zinc and lead are not disposed to unite; but a little arsenic occasions them to combine.

Of the alloys of copper and lead, Mr. Holtzapffel gives the following description:—

LEAD ALLOYS. — Two ounces lead to one pound copper produces a red-coloured and ductile alloy.

Four ounces lead to one pound copper gives an alloy less red and ductile. Neither of these is so much used as the following, as the object is to employ as much lead as possible.

Six ounces lead to one pound copper is the ordinary pot-metal, called *dry pot-metal*, as this quantity of lead will be taken up without separating on cooling; this alloy is brittle when warmed.

Seven ounces lead to one pound copper forms an alloy which is rather short, or disposed to break.

Eight ounces lead to one pound copper is an inferior pot-metal, called *wet* pot-metal, as the lead partly oozes out in cooling, especially when the new metals are mixed; it is therefore always usual to fill the crucible in part with old metal, and to add new for the remainder. This alloy is very brittle when slightly warmed. More lead can scarcely be used, as it separates on cooling.

Antimony twenty parts and lead eighty parts form the printing-type of France; and lead and antimony are united in various proportions to form the type-metal of our printers. See TYPE-METAL.

Mr. James Nasmyth, in a letter to the "Athenæum" (No. 1176, p. 511), directed attention to the employment of lead, and its fitness as a substitute for all works of art hitherto executed in bronze or marble. He says the addition of about 5 per cent. of antimony to the lead will give it, not only great hardness, but enhance its capability to run into the most delicate details of the work.

Baron Wetterstedt's patent sheathing for ships consists of lead, with 2 to 8 per cent. of antimony; about 3 per cent. is the usual quantity. The alloy is rolled out into sheets.—*Holtzapffel.* We are not aware that this alloy has ever been employed.

Digitized by Google

Emery wheels and grinding tools for the lapidary are formed of an alloy of antimony and lead.

Organ pipes are sometimes made of lead and tin, the latter metal being employed to harden the lead. The pipes, however, of the great organ in the Town Hall at Birmingham are principally made of sheet zinc.

Lead and arsenic form shot-metal. The usual proportions are said to be 40 lbs. of metallic arsenic to one ton of lead.

Tabular Statement of the Physical Peculiarities of the Principal Alloys, adopted, with some alterations, from the "Encyclopédie Technologique."

BRITTLE METALS.		
ARSENIC.	ANTIMONY.	BISMUTH.
With ZINC, rendering it brittle.	This alloy is very brittle.	Unknown.
With IRON and STEEL, hardening, whitening, and rendering those metals susceptible of a fine polish: much used for steel chains and other ornaments.	30 of iron and 70 of antimony are fusible; very hard, and white. An alloy of two of iron and one of antimony is very hard and brilliant.	Doubtful.
With GOLD, a grey metal, very brittle.	Forms readily a pale-yellow alloy, breaking with a fracture like porcelain.	Similar to antimony; of a yellow-green colour.
With COPPER. Composed of 62 parts of copper and 32 arsenic, a grey, brilliant, brittle metal. Increasing the quantity of copper, the alloy becomes white and slightly ductile: used in the manufacture of buttons under the name of white copper, or TOMBAC.	Alloys readily: the alloys are brittle. Those formed with equal parts of the two metals are of a fine violet colour.	Pale-red brittle metal.
With SILVER. 23 of silver and 14 arsenic form a greyish-white brittle metal.	These have a strong affinity; their alloys are always brittle.	Alloys brittle and lamellated.
With LEAD. Arsenic renders lead brittle. The combination is very intimate; not decomposed by heat.	Antimony gives hardness to lead. 24 parts of antimony and 76 of lead, corresponding to Pb^2Sb, appear the point of saturation of the two metals.	The alloys of bismuth and lead are less brittle and more ductile than those with antimony; but the alloy of 3 parts of lead and 2 of bismuth is harder than lead. These alloys are very fusible.
With TIN. Brittle, grey, lamellated; less fusible than tin.	The alloys of antimony and tin are very white. They become brittle when the arsenic is in large quantity.	Tin and bismuth unite in all proportions by fusion. All the alloys are more fusible than tin.
With MERCURY. Without interest.	A gritty white alloy.	Mercury dissolves a large quantity of bismuth without losing its fluidity; but drops of the alloy elongate, and form a tail.

DUCTILE METALS.			
IRON.	GOLD.	COPPER.	SILVER.
With ZINC. See GALVANISED IRON.	A greenish-yellow alloy, which will take a fine polish.	See BRASS.	Silver and zinc combine easily, forming a somewhat brittle alloy.
With IRON or STEEL.	Gold and iron alloy with ease, and form yellowish alloys, varying in colour with the proportions of the metals. Three or four parts of iron united with one of gold is very hard, and is used in the manufacture of cutting instruments.	Iron and copper do not form true alloys. When fused together, the iron, however, retains a little copper.—Several methods for coating iron with copper and brass will be described.	When 1 of silver and 500 of steel are fused, a very perfect button is formed.— *Stodart and Faraday.*
With GOLD - -	- - - - - - -	Copper and gold alloy in all proportions, the copper giving hardness to the gold. This alloy is much used in coin and in the metal employed in the manufacture of jewellery.	Gold and silver mix easily together; but they do not appear to form a true combination. Jewellers often employ *l'or vert*, which is composed of 70 parts of gold and 30 of silver, which corresponds very nearly to the alloy possessing the maximum hardness.
With COPPER -	- - - - - - -	- - - - -	Silver and copper alloy in all proportions. These alloys are much used in the arts. The maximum hardness appears to be produced when the alloy contains a fifth of copper.
With LEAD, does not appear to form any alloy.	A very brittle alloy. A thousandth pt. of lead is sufficient to alter the ductility of gold.	Do not appear to form a true alloy.	Unite in all proportions; but a very small quantity of lead will greatly diminish the ductility of silver.
With TIN. A very little iron diminishes the malleability of tin, and gives it hardness.	The alloys of gold and tin are brittle; they preserve, however, some ductility when the proportion of tin does not exceed $\frac{1}{12}$.	Of great importance. See BRONZE.	Alloys readily. A very small quantity of tin destroys the ductility of silver.
With MERCURY. Mercury has no action on iron.	Mercury has a most powerful action on gold. See AMALGAM.	An amalgam which is formed with difficulty, and without interest.	The amalgamation of these two metals is a little less energetic than between mercury and gold. See AMALGAMATION.

Digitized by Google

In addition to these, the alloys of iron appear of sufficient importance to require some further notice.

IRON and MANGANESE. Mr. Mushet concludes, from his experiments, that the maximum combinations of manganese and iron is 40 of the former to 100 of the latter. The alloy 71·4 of tin and 28·6 of manganese is indifferent to the magnet.

IRON and SILVER; STEEL and SILVER.—Various experiments have been made upon alloys of iron and steel with other metals. The only alloys to which sufficient importance has been given are those of iron and silver and steel and silver. M. Guyton states, in the "Annales de Chimie," that he found iron to alloy with silver in greater quantity than the silver with the iron. "Iron can," he says, "therefore no longer be said to refuse to mix with silver; it must, on the contrary, be acknowledged that those two metals, brought into perfect fusion, contract an actual chemical union; that, whilst cooling, the heaviest metal *separates for the greatest part;* that notwithstanding each of the two metals retains a portion of the other, as is the case in every liquation, that the part that remains is not simply mixed or interlaid, but chemically united; lastly, that the alloy in these proportions possesses peculiar properties, particularly a degree of hardness that may render it extremely useful for various purposes."

The experiments of Faraday and Stodart on the alloys of iron and steel are of great value; the most interesting being the alloy with silver. The words of these experimentalists are quoted:—

"In making the silver alloys, the proportion first tried was 1 silver to 160 steel; the resulting buttons were uniformly steel and silver in fibres, the silver being likewise given out in globules during solidifying, and adhering to the surface of the fused button; some of these, when forged, gave out more globules of silver. In this state of mechanical mixture the little bars, when exposed to a damp atmosphere, evidently produced voltaic action; and to this we are disposed to attribute the rapid destruction of the metal by oxidation, no such destructive action taking place when the two metals are chemically combined. These results indicated the necessity of diminishing the quantity of silver, and 1 silver to 200 steel was tried. Here, again, were fibres and globules in abundance; with 1 to 300 the fibres diminished, but still were present; they were detected even when 1 to 400 was used. The successful experiment remains to be named. When 1 of silver to 500 steel were properly fused, a very perfect button was produced; no silver appeared on its surface; when forged and dissected by an acid, no fibres were seen, although examined by a high magnifying power. The specimen forged remarkably well, although very hard; it had in every respect the most favourable appearance. By a delicate test every part of the bar gave silver. This alloy is decidedly superior to the very best steel; and this excellence is unquestionably owing to a combination with a minute quantity of silver. It has been repeatedly made, and always with equal success. Various cutting tools have been made from it of the best quality. This alloy is, perhaps, only inferior to that of steel and rhodium, and it may be procured at small expense; the value of silver, where the proportion is so small, is not worth naming; it will probably be applied to many important purposes in the arts."

Messrs. Faraday and Stodart show from their researches that not only silver, but platinum, rhodium, gold, nickel, copper, and even tin, have an affinity for steel sufficiently strong to make them combine chemically.

IRON and NICKEL unite in all proportions, producing soft and tenacious alloys. Some few years since, Mr. Nasmyth drew attention to the combination of silicon with steel. Fresh interest has been excited in this direction by the investigations of a French chemist, M. St. Claire Deville, who has examined many of the alloys of silicon. For other alloys of iron, see IRON.

SILICON and IRON combine to form an alloy which is a sort of fusible steel in which carbon is replaced by silicon. The siliciurets are all of them quite homogeneous, and are not capable of being separated by liquation.

COPPER and SILICON united in various proportions, according to the same chemist. A very hard, brittle, and white alloy, containing 12 per cent. of silicon, is obtained by melting together three parts silico-fluoride of potassium, one part sodium, and one part of copper, at such a temperature that the fused mass remains covered with a very liquid scoria. The copper takes up the whole of the silicon, and remains as a white substance less fusible than silicon, which may serve as a base for other alloys. An alloy with 5 per cent. silicon has a beautiful bronze colour, and will probably receive important applications.

Mr. Oxland and Mr. Truran have given, in "Metals and their Alloys," the following useful tabular view of the composition of the alloys of copper. In addition to those given, the alloy of copper and aluminium is now most important. See ALUMINIUM BRONZE.

ALLOY, NATIVE. OSMIUM and IRIDIUM, in the proportions of 72·9 of the former and 24·5 of the latter. See OSMIUM, IRIDIUM.

ALLSPICE. Pimento, or Jamaica pepper, so called because its flavour is thought to comprehend the flavour of cinnamon, cloves, and nutmegs. The tree producing this spice (*Eugenia pimenta*) is cultivated in Jamaica in what are called Pimento walks. It is imported in bags, almost entirely from Jamaica. Mr. Montgomery Martin informs us that pimento was exported in one year (1837) from the different districts of Jamaica as follows. (See PIMENTO, PEPPER.)

Kingston and Old Harbour	6027 bags.
Morant Bay and Port Morant	141 „
Port Antonio	1259 „
Port Marva and Annotto Bay	3194 „
Falmouth, Rio Bueno, and St. Ann's Bay	28188 „
Montego Bay and Lucca	3106 „
Sav-la-Mar and Black River	3622 „

ALLUVIUM. (*Alluo*, to wash upon; or *alluvio*, an inundation.) Earth, sand, gravel, stones, and other transported matter which has been washed away, and thrown down—by rivers, floods, or other causes—upon land not *permanently* submerged beneath the waters of lakes or seas.—*Lyell.*

ALLYLAMINE. See ACRYLAMINE.

ALMANDINE, or iron-garnet, is a silicate of alumina and iron, combined in the following proportions: silica 36·3, alumina 20·56, protoxide of iron 43·2.

It occurs in Greenland, Ceylon and the Brazils; when cut and polished, it forms a beautiful gem.

The name is probably derived from the Alabandic carbuncles of Pliny, which were cut and polished at Alabande. See GARNET.

ALMOND. (*Amande*, Fr.; *Mandelus*, Germ.; *Amygdal communis.*) De Candolle admits five varieties of this species. *Aamara*, bitter almond; *A. dulcis*, sweet almond; *A. fragilis*, tender-shelled almond; *A. macrocarpa*, large-fruited almond; *A. persicoides*, peach almond. There are two kinds of almond usually employed, which do not differ in chemical composition, only that the bitter, by a curious chemical reaction of its constituents, generates in the act of distillation a quantity of volatile oil which contains hydrocyanic acid. Vogel obtained from bitter almonds 8·5 per cent. of

Digitized by Google

husks. After pounding the kernels, and heating them to coagulate the albumen, he procured, by expression, 28 parts of an unctuous oil, which did not contain the smallest particle of hydrocyanic acid. The whole of the oil could not be extracted in this way. The expressed mass, treated with boiling water, afforded sugar and gum, and, in consequence of the heat, some of that acid. The sugar constitutes 6·5 per cent. and the gum 3. The vegetable albumen extracted, by means of caustic potash, amounted to 30 parts: the vegetable fibre to only 5. The poisonous aromatic oil, according to Robiquet and Boutron-Charlard, does not exist ready-formed in the bitter almond, but seems to be produced under the influence of ebullition with water. These chemists have shown —

1st. That neither bitter almonds nor their residuary cake yield any volatile oil by pressure.

2nd: They yield no oil when digested in alcohol or in ether, though the volatile oil is soluble in both these liquids.

3rd. Alcohol extracts from bitter-almond cake, sugar, resin, and *amygdalin*; when the latter substance has been removed, the cake is no longer capable of furnishing the volatile oil by distillation.

4th. Ether extracts no amygdalin, and the cake left, after digestion in ether, yields the volatile oil by distillation with water; but alcohol dissolves out a peculiar white crystalline body, without smell, of a sweetish taste at first, and afterwards bitter, to which they gave the name of *amygdaline*. This substance does not seem convertible into volatile oil. — *Pereira*. See Watts' "Dictionary of Chemistry."

Sweet almonds, by the analysis of Boullay, consist of 54 parts of the bland almond oil, 6 of unerystallisable sugar, 3 of gum, 24 of vegetable albumen, 24 of woody fibre. 5 of husks, 3·5 of water, 0·5 of acetic acid, including loss. We thus see that sweet almonds contain nearly twice as much oil as bitter almonds do.

Three varieties are known in commerce.

1. *Jordan Almonds* which are the finest, come from Malaga. Of these there are two kinds; the one above an inch in length, flat, with a clear brown cuticle, sweet, mucilaginous, and rather tough; the other more plump and pointed at one end, brittle, but equally sweet with the former.

2. *Valentia almonds* are about three-eighths of an inch broad, not quite an inch long, round at one end, and obtusely pointed at the other, flat, of a dingy brown colour and dusty cuticle.

3. *Barbary and Italian almonds* resemble the latter, but are generally smaller and less flattened. — *Brande, Dictionary of Pharmacy.*

Our *Importation* of ALMONDS in 1863 was as follows:—

Sweet Almonds, 34,358 cwt., valued at 109,595*l.*; and of Bitter Almonds 11,312 cwt., valued at 22,624*l.*

ALMOND OIL, BITTER. *Oil of bitter almonds. Essential oil of bitter almonds.* (*Oleum Amygdalæ Amaræ*).

After the fixed oil has been expressed from the bitter almonds, the residual cake is mixed with water and distilled. A volatile oil comes over. It has been convincingly proved that this fine-flavoured essential oil is produced during the process, by some decomposition of the amygdalin and the emulsin of the seeds. It is highly poisonous, owing to the presence of hydrocyanic acid. See BENZOIC ACID, BENZOLE, &c.

ALMOND OIL, SWEET. A bland fixed oil, obtained by expression from bitter or sweet almonds—usually from the former, on account of their cheapness as well as the greater value of the residual cake. The average produce is from 48 to 52 lbs. from 1 cwt. of almonds.

This is commonly known as *Oil of sweet almonds*, the *Oleum Amygdalæ* of the Pharmacopœia. When first obtained it is opaque, and of a yellow colour; but it speedily becomes quite transparent, and is bleached by exposure to light. This oil has a bland taste, and does not congeal at a temperature which solidifies olive-oil. It is often sold for nut-oil, which is supposed to possess this property of remaining fluid in an eminent degree.

ALMOND POWDER (*farina amygdalæ*) is the ground almond-cake; it is employed for washing the hands, and as a lute.

ALOE. (*Aloës*, Fr.; *Glauindes aloe*, Germ.) In botany a genus of the class *Hexandria monogynia*. There are many species, all natives of warm climates.

In Africa the leaves of the Guinea aloe are made into durable ropes. Of one species are made lines, bowstrings, stockings, and hammocks; the leaves of another species are used to hold rainwater. A series of trials has been made, within a few years, in Paris, to ascertain the comparative strength of cables made of hemp and of the aloe from Algiers; and they are said to have all turned to the advantage of the

Digitized by Google

aloe. Of cables of equal size, that made of aloe raised a weight of 2,000 kilogrammes (2 tons nearly), that made of hemp a weight of only 400 kilogrammes.—*Ure.*

The following varieties of the inspissated juices of the Aloe—called ALOES, and often BITTER ALOES—are known in commerce: *Socotrine, Hepatic, Barbados, Cape, Mocha, Catalline, and Indian.* The Socotrine Aloes are regarded as the best kind, but that from Barbados is the most abundant, and much of it is sold as Socotrine. The Barbados Aloes are imported from Barbados or Jamaica, usually in gourds weighing from 60 to 70 pounds, but sometimes in boxes holding about half a hundredweight.

Our importation of aloes and their declared value, in 1863, has been:

	lbs.	Per Cwt. £ s. d.	£
From Egypt	18,947	5 0 0	846
South Africa	449,395	2 4 11	8,823
India and Ceylon	189,356	7 4 8	12,231
British West Indies	29,669	10 0 0	2,650
Other parts	20,938	6 2 5	1,145
	699,305		25,695

A patent was taken (January 27, 1847) for certain applications of aloes to dyeing. Although it has not been employed, the colouring matter so obtained promising to be very permanent and intense, it is thought advisable to describe the process by which it is proposed to prepare the dye. It is as follows:—

Into a boiler or vessel capable of holding about 100 gallons, the patentee puts 10 gallons of water, and 132 lbs. of aloes, and heats the same until the aloes are dissolved; he then adds 80 lbs. of nitric or nitrous acid in small proportions at a time, to prevent the disengagement of such a quantity of nitrous gas as would throw part of the contents out of the boiler. When the whole of the acid has been introduced, and the disengagement of gas has ceased, 10 lbs. of liquid caustic soda, or potash of commerce, of about 30°, are added to neutralise any undecomposed acid remaining in the mixture, and to facilitate the use of the mixture in dyeing and printing. If the colouring matter is required to be in a dry state, the mixture may be incorporated with 100 lbs. of china-clay and dried in stoves, or by means of a current of air. The colouring matter is used in dyeing by dissolving a sufficient quantity of water, according to the shade required, and adding as much hydrochloric acid or tartar of commerce as will neutralise the alkali contained in the mixture, and leave the dye-bath slightly acidulated. The articles to be dyed are introduced into the bath, which is kept boiling until the desired shade is obtained.

When the colouring matter is to be used in printing, a sufficient quantity is to be dissolved in water, according to the shade required to be produced; this solution is to be thickened with gum, or other common thickening agent, and hydrochloric acid, or tartar of commerce, or any other suitable supersalt, is to be added thereto. After the fabrics have been printed with the colouring matter, they should be subjected to the ordinary process of steaming, to fix the colour.—*Napier.*

ALOETIC ACID. The colouring matter of the aloes depends on this acid, which has been examined by Schunck and Mulder. Aloetic acid is deposited, from nitric acid which has been heated with aloes, as a yellow powder: it dissolves in ammonia with a violet colour; when treated with protochloride of tin it forms a dark-violet heavy powder; and this again, when treated with potash, evolves ammonia, and assumes a violet-blue colour. This solution of aloetic acid in ammonia is violet.

ALPACA. (*Alpaga*, Fr.) An animal of Peru, of the Llama species; also the name given to a woollen fabric woven from the wool of this animal, or a mixture of silky goats' hair with the harsher fibre of sheeps' wool. See LLAMA.

ALUDEL. The aludels of the earlier chemists were a series of pear-shaped pots, generally made of earthenware, but sometimes of glass, open at both ends. Each aludel had a short neck at top and bottom, so that a series of them could be fitted together, by means of the neck, in succession.

ALUM. (*Alun*, Fr.; *Alaun*, Germ.) A saline body or salt, consisting of alumina, or the peculiar earth of clay, united with sulphuric acid, and these again united with sulphate of potash or ammonia. In other words, it is a double salt, consisting of sulphate of alumina and sulphate of potash, or sulphate of alumina and sulphate of ammonia. The common alum crystallises in octahedrons, but there is a kind which takes the form of cubes. It has a sour or rather subacid taste, and is peculiarly astringent. It reddens the blue colour of litmus or red cabbage, and acts like an

Digitized by Google

acid on many substances. Other alkalis may take the place of the ammonia or potash, and other metals that of the aluminium.

Alum was known to the ancients, who used it in medicine, as it is now used, and also as a mordant in dyeing and calico printing, as at the present day. Old historians do not describe correctly, either the mode of obtaining it or its exact characteristics, so that it is confounded with sulphate of iron, with which it seems generally to have been mixed. But that some qualities were made with very little iron in it, is clear from the fact that it was employed when white for dyeing bright colours. (*Pliny*, xxxv. 15.) It is said by Pliny that the purchasers tested it with tannin (pomegranate juice), in order to see if it blackened. He says that the white kind blackened as well as the black; but in all probability this was a test applied by the dyers to see which blackened least, so as to obtain a good mordant for reds. Pliny's description, although confused, leaves this fact perfectly clear — that there were men in whose minds the knowledge was much clearer than in his, or a manufacture of such magnitude could not have existed. There is mention of some being made from stone, and crystallising in fine hairs, but the characteristics given do not enable us to decide that this was either alum or the peculiar sulphate of alumina which takes that form. The alum was sometimes boiled down to dryness, and heated till it was spongy or like pumice-stone. It was used as burnt alum.

They used it also for preventing the combustibility of wood and wooden buildings. But although the knowledge of it was very accurate, their writers always imagine that sulphate of iron was a kind of alum, because it is said that the black alum was used for dyeing dark colours. They used iron as a mordant, and found its character by galls or by pomegranate juice, which contains tannin. Their alum was chiefly a natural production, and they removed the fine efflorescing crystals which first appeared, or which gradually are raised above the rest, as the finest kind. "It was produced in Spain, Egypt, Armenia, Macedonia, Pontus, and Africa; the islands Sardinia, Melos, Lipari and Stromboli. The best was got in Egypt, the next in Melos." The word is probably Egyptian, as it was best and most abundantly obtained in Egypt. It is not probable that it was the double salt in all cases, but simply a sulphate of alumina. Pliny, indeed, says that a substance called in Greek Τυρά, or watery, probably from its very soluble nature, and which was milk-white, was used for dyeing wool of bright colours. This may have been the mountain butter of the German mineralogists, which is a native sulphate of alumina, of a soft texture, waxy lustre, and unctuous to the touch. The *stypteria* of Dioscorides and the *alumen* of Pliny comprehended, no doubt, a variety of saline substances besides sulphate of iron and alum.

It seems to have come to Europe in later times as alum of Rocca, the name of Edessa, or that place where the Italians first learnt the art; but it is not impossible that this name was an Italian prefix, which has remained to this day under the form of Rock alum, *Rotzalaun* and *Alun de Roche*. The East has always had some manufactures of it, and Phocis, Lesbos, and other places, were able to supply the Turks with alum for their magnificent Turkey red. It was also made at Foya Nova, near Smyrna, and at Constantinople. The Genoese and other trading people of Italy imported alum into Western Europe for the use of the dyers of red cloth.

A Genoese merchant, Bartholomew Perdix, who had been in Syria, observed a stone suitable for alum in the island Ischia; he burnt it, and obtained a good result, being the first who introduced the manufacture into Europe. This was in the year 1459; about the same time John di Castro learnt the method at Constantinople, and manufactured alum at Tolfa. This discovery of the mineral near Civita Vecchia was considered so important by John di Castro, that he announced it to the Pope as a great victory over the Turks, who annually took from the Christians 300,000 pieces of gold for their dyed wool. A statue was erected to the "Discoverer of Alum."—*Beckman*.

The manufacture of alum was then made a monopoly of the Papal Powers, and instead of buying it as before from the East, it was considered Christian to obtain it only from the States of the Church, and, as such, was made compulsory in the West. The manufacture then went to Spain, to a spot near Carthagena. Germany began so early as 1554 to make alum, although Basil Valentine seems to have known of its existence there somewhat sooner. The first establishment known was at Oberkaufungen in Hesse-Cassel, where it still exists. It was not introduced as a manufacture into England until the year 1600, when Sir Thomas Chaloner, the son of queen Elizabeth's minister of that name, found that his own estate of Guisborough, in Yorkshire, contained alum. This he is said first to have observed from the vegetation, which had a very weak green. Di Castro had first been led to it by the appearance of the holly, but neither can be said to be decisive tests of its presence, nor are the geological features of Tolfa and Guisborough at all like. The violent denunciations of the Pope

Digitized by Google

did not prevent the manufacture from growing to unexpected magnitude in England. The mines of the same district have ever since sent out alum, which is now known as Whitby alum, and even those at Guisborough itself are now at work, although for seventy years of the period since their discovery they were disused. The manufacture was begun at Hurlet, in Scotland, by Nicholson and Lightbody, in 1766, abandoned, and resumed by Macintosh and Wilson in 1797.

The composition of alum is expressed by chemists in the following manner: $Al^2O^3\ 3SO^3\ KOSO^3\ 24HO$. This peculiar combination is that of the original substance as far as it appeared to the chemists of last century, and the form is now held as a type, after which many other alums are composed. Ammonia-alum was occasionally made, even as early as Agricola's time, 16th century. Its composition is $Al^2O^3\ 3SO^3\ NH^4OSO^3 + 24HO$. The same thing occurs with soda; soda-alum is $Al^2O^3\ 3SO^3\ NaOSO^3 + 24HO$. Every salt having this form is called an alum. Sometimes, instead of the alkali being changed, the earth is changed. Thus we have chrome-alum, $Cr^2O^3 3SO^3\ KOSO^3 + 24HO$; or we have an iron-alum, $Fe^2\ O^3\ 3SO^3\ KOSO^3 + 24HO$. These may be varied to a great extent, but all have a characteristic of alum. The twenty-four atoms of water are one of the peculiar characteristics.

„	167	„	„	0·1	„
„	189·5	„	„	0·06	„

A solution saturated at 46° is 1·045 specific gravity. This difference in the rate of solubility in hot and cold water renders it easily separated from many other salts. The crystals are permanent in the air, or nearly so, unless the air be very dry; if kept at 180° they lose 18 atoms of water, but alum deprived of its water and exposed to the air of summer took up 18 atoms in 47 days. It melts at a low temperature in its water of crystallisation. At 356° it loses 43·5 per cent. of water, or 23 atoms; the last atom is only lost when approaching red heat. At a red heat the sulphate of alumina loses its acid, and the alumina seems then able to remove some acid from the potash, losing it again by heat. Alum, when heated with common salt, acts like sulphuric acid, and gives off muriatic acid; the same with chlorides of potassium and ammonium. If boiled with a saturated solution of chloride of potassium, hydrochloric acid is formed and a subsulphate of alumina falls down; this occurs only to a small extent with chloride of sodium, and still less with sal-ammoniac.

Ammonia Alum contains:—

Ammonia - - - - - - -	3·75 per cent.
Alumina - - - - - - -	11·34 „
Sulphuric acid - - - - - -	35·29 „
Water - - - - - - - -	49·62 „
	100·00

This salt also occurs in octahedrons, and can only be known from potash-alum by trial. The addition of caustic lime, soda, or potash gives out the ammonia, easily distinguished by the smell. Soda-alum is not an article of commerce, nor is it used

Digitized by Google

in the arts. The addition of ammonia to a solution of alum, or the addition of any other alkali, in insufficient quantity, causes a precipitate, not of pure alumina, as one might suppose, but of a subsulphate of alumina. Even an excess of alkali will not remove all the sulphuric acid without heat being applied; an excess, on the other hand, is apt to dissolve some of the alumina, especially if few salts are present, and the solution not much boiled. Sulphide of ammonium precipitates it thoroughly.

Ammonia-alum readily loses all its ammonia when heated, and the sulphuric acid may be driven off the remaining sulphate of alumina, so that the pure earth-alumina will remain.

In commerce ammonia- and potash-alums are sometimes found mixed.

Applications of Alum.—Alum is an astringent. Its immediate effect on man is to corrugate the fibres and contract the small vessels. It precipitates albuminous liquids and combines with gelatine. It causes dryness of the mouth and throat, and checks the secretions of the alimentary canal, producing constipation—in large quantities, nausea, vomiting, purging. It is given in lead colic, to convert the lead into sulphate of lead, and is used externally. Its principal use is in dyeing; calico-printers print it as a mordant; the cloth is then put into the dye, and the printed parts absorb the colour. Paper-makers use it in their size and bookbinders in their paste. It is used in tanning leather, and sometimes, both in Asia and Europe, it is used for precipitating rapidly the impurities of water. This is a dangerous process, unless there be a great amount of alkaline salts, such as carbonate of lime or soda, to neutralise the acid. It is extensively used in correcting the baking qualities of bad flour, for which the experience of many has decided that it is a valuable remedy; unfortunately, it is also used to make excellent flour whiter, when there is no need of its presence. Liebig says that lime is equally good, and of course much safer. From time immemorial it has been used to prevent the combustibility of wood and cloth.

Alum heated with charcoal or carbonaceous substances forms Homberg's phosphorus, which inflames spontaneously. It is composed of alumina, sulphide of potassium, and charcoal.

Roman Alum crystallises—partly in octahedrons, like other alums, partly in cubes. If these cubes are dissolved in water of about 110° F., the evaporated liquid gives crystals of common or octahedral alum. It was said that on heating it deposited subsulphate of alumina; but Loewel says that such crystals were impure, and he finds no real difference of composition. All that seems to be known with certainty is, that it is formed when there is a salt of alumina in solution with the alum containing more alumina than the neutral or common alum. This can very readily occur in the Roman alum, where there is a great excess of alumina in the alum-stone. The Roman alum is prized for its great freedom from iron; it was said by MM. Thenard and Roard to contain only $\frac{1}{2500}$th of sulphate of iron, whilst the ordinary alum contained $\frac{1}{1000}$th.

Burnt Alum, or dried alum, is made by gently heating alum till the water is driven off. The alum first melts in its water of crystallization, and is then dried. It has a stronger action than the hydrated crystals, and is a mild escharotic. It reabsorbs water.

Neutral Alum is a name sometimes given erroneously to alum which has had some of its acid neutralised by an alkali. It is in fact a basic salt of alumina, which may also be made by dissolving alumina in ordinary alum. It deposits a basic salt more readily than ordinary alum, and may be of service in some cases of printing. Properly speaking, the common alum is the neutral salt.

Testing of Alum.—Alum being generally in large crystals, any impurity is more readily seen; this is said to be the reason for keeping up the practice of making this substance instead of the sulphate of alumina alone, which is less bulky and fitted for nearly every purpose for which alum is used. But probably the ancient accidental discovery of the potash form has determined its use to the present day. Iron is readily found in it, by adding to a dilute solution ferrocyanide of potassium or prussiate of potash, which throws down Prussian-blue. A very delicate test is sulphuret of ammonium, which throws down both the alumina and iron, but the blacking of the precipitate depends on the amount of iron. The total amount of iron is got by adding pure caustic potash or soda till the solution is strongly alkaline, washing and filtering off the oxide. To look for lime, precipitate the alumina and iron by ammonia, boil and filter—the lime and magnesia are in the solution—add oxalate of ammonia; add tartaric acid to keep up the iron and alumina, make alkaline by ammonia, then precipitate the lime by oxalate of ammonia, filter, and precipitate the magnesia by a phosphate. Silica and insoluble basic sulphates are obtained by simply dissolving the alum in water and filtering. If silica, it is insoluble in acids; if a basic sulphate, it will dissolve in sulphuric acid, and the addition of sulphate of potash or ammonia will convert it into potash- or ammonia-alum.

Pure alum gives a white precipitate with ammonia, no precipitate with sulphuretted hydrogen gas, and no precipitate with oxalate of ammonia and ammonia, if tartaric acid be previously added.

Digitized by Google

In a saturated solution of tersulphate of alumina, the crystals of alum are almost insoluble.

If we dissolve alum in 20 parts of water, and drop this solution slowly into water of caustic ammonia till this be nearly, but not entirely, saturated, a bulky white precipitate will fall down, which, when properly washed with water, is pure aluminous earth or clay; and, dried, forms 10·94 per cent. of the weight of the alum. If this earth, while still moist, be dissolved in dilute sulphuric acid, it will constitute, when as neutral as possible, simple sulphate of alumina, which requires only two parts of cold water for its solution. If we now decompose this solution, by pouring into it water of ammonia, there appears an insoluble white powder, which is subsulphate of alumina, or basic alum, and contains three times as much earth as exists in the neutral sulphate. If, however, we pour into the solution of the neutral sulphate of alumina a solution of sulphate of potash, a white powder will fall if the solutions be concentrated, which is true *alum*; if the solutions be dilute, by evaporating their mixture, and cooling it, crystals of alum will be obtained.

When newly precipitated alumina is boiled in a solution of alum, a portion of the earth enters into combination with the salt, constituting an insoluble compound which falls in the form of a white powder. The same combination takes place, if we decompose a boiling hot solution of alum with a solution of potash, till the mixture appears nearly neutral by litmus-paper. This insoluble or basic alum exists native in the alum stone of Tolfa, near Civita Vecchia, and it consists, in 100 parts, of 19·72 parts of sulphate of potash, 61·99 basic sulphate of alumina, and 18·29 water. When this mineral is treated with a due quantity of sulphuric acid, it dissolves, and is converted into the crystallisable alum of commerce.

Its formula, according to Graham, is a basic alum, $HO\,SO^3 + 3(Al^2\,O^3\,SO^3) + 9HO$. By losing alumina it becomes the neutral salt.

Sulphate of Alumina.—The first step towards the production of alum is the sulphate of alumina. This is found in various proportions in alum stone. The pure mineral has the following composition:—

1 atom of alumina	- -	15·42 per cent.
3 atoms of sulphuric acid	-	35·99 „
18 atoms of water	- -	48·59 „
		100·

There are many analyses of natural specimens closely approaching this. It is found crystallised in a close mass of fine, white, flexible needles, of a feather or hair form, and has been, like a few other substances, called hair-salt. It is also found with various degrees of impurity, sometimes with a smaller amount of water. Knapp has collected the following list of analyses:—

The manufacture of alum involves the making of sulphate of alumina in the first instance in all cases where potash is not present in the ore; for this reason the description of both is included in one article.

Ores or Raw Material.—The chief difficulty in manufacturing alum has been the solution of the alumina. This substance is generally combined with silica in such a strong combination, that even powerful acids cannot remove it without assistance. The older methods, however, took no notice of these difficulties, and obtained the alum more or less directly from nature. The method now practised at the Solfatara di Pozzuoli and the island Vulcano is simply to take the efflorescence and the earth containing it, wash it with water, and concentrate. But it very seldom contains a sufficient amount of potash to form alum. A salt of potash is then added, chiefly a carbonate. To transform this into a sulphate, a portion of the sulphate of alumina is decomposed. The use of a carbonate is a wasteful method of modern times; the ancients would have felt no difficulty, but boiled all down, and so obtained the whole alumina there. Their product, therefore, would have been basic sulphate of alumina, which it evidently was when this practice was resorted to. When they merely concentrated and then crystallised, they got pure alum; but they lost a great deal of their alumina.

At Tolfa the alum is obtained from a compact crystalline substance called alunite. The analysis of Cordier makes it a combination of alum with alumina. If treated with water only, it will not give out alum; but if moderately calcined, it breaks up, gives out a large amount of alum, and the liquid is then boiled down for crystallisation.

The following analyses show that some natural alum-ores contain a considerable amount of potash. As there is seldom enough of potash found, it must be added in the form of sulphate of potash or chloride of potassium :—

Sulphuric acid -	36·187 -	34·6 -	20·06
Alumina - -	35·105 -	40·0 -	39·70
Potash - - -	10·824 -	15·8 -	Lime 0·30
Water - - -	18·124 -	10·6 -	59·94
	100·240	100·0	120·00

These formations of alum are generally found where sulphurous gases are exhaled: under the action of which the rock is gradually decomposed.

It is not, however, found so rich in potash in the great majority of cases. The following are analyses of some other alum-stones :—

	Klaproth. Tolfa Alum Stone.	Klaproth. Beregszas Alum Stone.	Descotil. Montione.	Cordier. Mont d'Or.
Silica - - - - -	56·5	62·3	- -	28·4
Alumina - - - -	19·0	17·5	40·0	31·8
Sulphuric acid - - -	16·5	12·5	35·6	27·0
Potash - - - - -	4·0	1·0	13·8	5·8
Water - - - - -	3·0	5·0	10·0	3·7
Oxide of iron - - -	- -	- -	- -	1·4

When there is no silica, but only sulphuric acid, alumina, and potash, we have a natural alum, and in that case there is nothing to be done towards the manufacture. But it rarely happens that the constituents exist in a proportion to form the crystalline salt. There may be sulphate of alumina, hydrate of alumina, and some true alum, or sulphate of alumina and potash. This excess of hydrate of alumina forms, when united with the sulphate, a basic or insoluble sulphate of alumina, and nothing but the sulphate of potash becomes soluble. When the hydrate is heated the water escapes; the sulphate of alumina and potash are then capable of being washed out together, and alum is obtained. At Tolfa it is obtained in crystals, covered over with a light red powder of peroxide of iron. This reddish covering always accompanies the Roman or partly cubical alum, and it has been sometimes added in order to give common alum the appearance of the Roman.

As the principal difficulty in the manufacture of alum is the solution of the alumina, it is unfortunate that so much of the hydrate is destroyed, as in the process mentioned, when sulphuric acid would readily dissolve it and greatly increase the produce. By the method described to us the measure of alum is simply the amount of the potash. All that cannot find potash to unite with is lost.

M. Cordier gives the following as a specimen of one of the alum stones from which the alum is made at Tolfa:—

Sulphate of potash	18·53
Sulphate of alumina	38·50
Hydrate of alumina	42·97

To transform this compound into alum, it is necessary merely to remove the alumina. The ordinary aluminous stone, however, is rarely so pure as the above analysis would show.

Occasionally ammonia-alum is found in nature. Analyses have been made of specimens from Tschermig, in Bohemia, by Stromeyer:—

Alumina	11·602	Sulphate of alumina	38·688
Ammonia	3·721	Sulphate of ammonia	12·478
Magnesia	0·115	Sulphate of magnesia	0·337
Sulphuric acid	36·065	Water	48·390
Water	48·390		99·893
	99·893		

Soda-alum is also found naturally.

Protoxide of iron	0·760
	100·162

Alum occurs ready formed in nature in the alum stones of Italy, &c., as an efflorescence on stones, and in certain mineral waters in the East Indies. The alum of European commerce is manufactured artificially, either from the alum schists or stones, or from clay. The mode of manufacture differs according to the nature of these earthy compounds. Some of them, such as the alum stone, contain all the elements of the salt, but mixed with other matters, from which it must be freed. The schists contain only the elements of two of the constituents, namely, clay and sulphur, which are convertible into sulphate of alumina, and this may be then made into alum by adding the alkaline ingredient. To this class belong the alum slates, and other analogous schists, containing brown coal.

1. *Manufacture of Alum from the Alum Stone.*—The alum stone is a rare mineral, being found in moderate quantity at Tolfa, and in larger in Hungary, at Beregszaz, and Muszag, where it forms entire beds in a hard substance, partly characterised by numerous cavities, containing drusy crystallisations of alum stone or basic alum. The larger lumps contain more or fewer flints disseminated through them, and are, according to their quality, either picked out to make alum, or thrown away. The sorted pieces are roasted or calcined, by which operation apparently the hydrate of alumina, associated with the sulphate of alumina, loses its water and its affinity for alum. It becomes, therefore, free; and during the subsequent exposure to the weather the stone gets disintegrated, and the alum becomes soluble in water.

The calcination is performed in common lime kilns in the ordinary way. In the regulation of the fire it is requisite, here, as with gypsum, to prevent any fusion or running together of the stones, or even any disengagement of sulphuric or sulphurous acids, which would cause a corresponding diminution in the produce of alum. For this reason the contact of the ignited stones with carbonaceous matter ought to be avoided.

The calcined alum stones, piled in heaps from 2 to 3 feet high, are to be exposed to the weather, and meanwhile they must be continually kept moist by sprinkling

Digitized by Google

them with water. As the water combines with the alum the stones crumble down, and fall, eventually, into a pasty mass, which must be lixiviated with warm water, and allowed to settle in a large cistern. The clear supernatant liquor, being drawn off, is to be evaporated, and then crystallised. A second crystallisation finishes the process, and furnishes a marketable alum. Thus the Roman alum is made, which is covered with a fine red film of peroxide of iron.

Sulphate of alumina occurs sometimes in union with sulphate of iron. In the Hurlet and Campsie coal beds a salt has been found with a variable composition, of which four specimens are here given.

This was a kind of feather alum or hair salt.

2. *Alum Manufacture from Alum Schist.*—The greater portion of the alum found in British commerce is made from alum slate and analogous minerals. This slate contains more or less iron pyrites, mixed with coaly or bituminous matter, which is occasionally so abundant as to render the schist somewhat combustible. In the strata of brown coal and bituminous wood, where the upper layers lie immediately under clay beds, they consist of the coaly substance rendered impure with clay and pyrites. This triple mixture constitutes the essence of all good alum schists, and it operates spontaneously towards the production of sulphate of alumina. The coal, besides burning, serves to make the texture open, and to allow the air and moisture to penetrate freely, so as to change the sulphur and iron present into acid and oxide. When these schists are exposed to a high temperature in contact with air, the pyrites loses one half of its sulphur, in the form of sublimed sulphur or sulphurous acid, and becomes a black sulphuret of iron, which speedily attracts oxygen, and changes to sulphate of iron, or green vitriol. The brown coal schists contain, commonly, some green vitriol crystals spontaneously formed in them. The sulphate of iron transfers its acid to the clay, progressively, as the iron, by the action of the air with a little elevation of temperature, becomes peroxidised; whereby sulphate of alumina is produced. A portion of the green vitriol remains, however, undecomposed, and so much the more as there may happen to be less of other salifiable bases present in the clay slate. Should a little magnesia or lime be present, the vitriol gets more completely decomposed, and a portion of Epsom salt and gypsum is produced.

The production of alum from alum stone, in which the whole ingredients have been found, has been far from enough for the supply of the world, and recourse has been had to substances very different in composition,—alum shale, or schist, and clay. Until within a few years the only supply of alum in Britain has been from the lias shales of Whitby, and the lower coal measures of Campsie and Hurlet, near Glasgow, and they are still the only places where it is manufactured from the ore, as it is called.

The manufacture of alum from alum schists may be described under the six following heads:—The preparation of the alum shale. 2. The lixiviation of the shale. 3. The evaporation of the lixivium. 4. The addition of the saline ingredients, or the precipitation of the alum. 5. The washing of the aluminous salts; and, 6. The crystallisation.

1. *Preparation of the Alum Shale.* — Some alum shales are of such a nature that, being piled in heaps in the open air, and moistened from time to time, they get spontaneously hot, and by degrees fall into a pulverulent mass, ready to be lixiviated. The greater part, however, require the process of ustulation, from which they derive many advantages. The cohesion of the dense shale is thereby so much impaired that its decomposition becomes more rapid; the decomposition of the pyrites is quickened by the expulsion of a portion of the sulphur; and the ready-formed green vitriol is partly decomposed by the heat, with a transference of its sulphuric acid to the clay, and the production of sulphate of alumina.

Such alum shales as contain too little bitumen or coal for the roasting process must be interstratified with layers of small coal or brushwood over an extensive surface. At Whitby the alum-rock, broken into small pieces, is laid upon a horizontal bed of

Digitized by Google

fuel, composed of brushwood; but at Hurlet small coal is chiefly used for the lower bed. When about four feet of rock is piled on, fire is set to the bottom in various parts; and whenever the mass is fairly kindled, more rock is placed over the top. At Whitby this piling process is continued till the calcining heap is raised to the height of 90 or 100 feet. The horizontal area is also augmented at the same time till it forms a great bed nearly 200 feet square, having therefore about 100,000 yards of solid measurement. The rapidity of the combustion is tempered by plastering up the crevices with small schist moistened. When such an immense mass is inflamed, the heat is sure to rise too high, and an immense waste of sulphur and sulphuric acid must ensue. This evil has been noticed at the Whitby works. At Hurlet the height to which the heap is piled is only a few feet, while the horizontal area is expanded: which is a much more judicious arrangement. At Whitby 130 tons of calcined schist produces on an average 1 ton of alum. In this humid climate it would be advisable to pile up on the top of the horizontal strata of brushwood or coal and schist, a pyramidal mass of schist, which, having its surface plastered smooth, with only a few air-holes, will protect the mass from the rains, and at the same time prevent the combustion from becoming too vehement. Should heavy rains supervene, a gutter must be scooped out round the pile for receiving the aluminous lixivium, and conducting it into the reservoir.

It may be observed, that certain alum schists contain abundance of combustible matter, to keep up a suitable calcining heat after the fire is once kindled; and therefore nothing is needed but the first layer of brushwood, which, in this case, may be laid over the first bed of the bituminous schist.

A continual but very slow heat, with a smothered fire, is most beneficial for the ustulation of alum-slate. When the fire is too brisk, the sulphuret of iron may run with the earthy matters into a species of slag, or the sulphur will be dissipated in vapour, by both of which accidents the product of alum will be impaired. Those bituminous alum schists which have been used as fuel under steam boilers have suffered such a violent combustion that their ashes yield almost no alum. Even the best regulated calcining pipes are apt to burn too briskly in high winds, and should have their draught-holes carefully stopped under such circumstances. It may be laid down as a general rule, that the slower the combustion the richer the roasted ore will be in sulphate of alumina. When the calcination is complete, the heap diminishes to one-half its original bulk; it is covered with a light reddish ash, and is open and porous in the interior, so that the air can circulate freely throughout the mass. To favour this access of air, the masses should not be too lofty; and in dry weather a little water should be occasionally sprinkled on them, which, by dissolving away some of the saline matter, will make the interior more open to the atmosphere.

Messrs. Richardson and Ronalds have given some very minute analyses of the Whitby and Campsie shales.

When alum is made of such shale, the object is first of all to oxidise the sulphur, forming sulphuric acid. This acid then dissolves the alumina. The result may be accomplished by allowing the shale to disintegrate spontaneously in the air, the sulphur oxidising and dissolving the alumina. But in general, as at Whitby and Campsie, combustion must be resorted to. This can be accomplished without the use of coal, further than is needful simply to set fire to that portion which exists in the shale itself. Indeed, the Campsie one, having more coal than is desirable for slow combustion, is mixed with some spent material, in order to diminish the force of the heat.

The sulphur is united with the iron, forming a bisulphuret, each atom of which must therefore take up seven atoms of oxygen, $FeS^2 + 7O = FeO\,SO^3 + SO^3$. When combustion takes place, the sulphur oxidises: if rapid combustion is used, then sulphurous acid gas escapes; if slow combustion, the sulphurous acid penetrates the mass slowly, receives another atom of oxygen, unites to a base, and a sulphate is the consequence. Sulphate of iron is formed and pure sulphuric acid. In the process it is probable that the oxidation is completed by means of the iron. Protoxide of iron readily becomes peroxide; the sulphurous acid readily decomposes peroxide, forming sulphuric acid and protoxide of iron. This protoxide of iron is again converted into peroxide, and if not dissolved is rendered, to a great extent, difficult to dissolve, by reason of the heat of the mass. For this reason partly, there is less sulphate of iron in the alum than might be expected. To effect these changes it is desirable to burn very slowly, so as to allow no loss of sulphurous acid, and, in washing, to allow the water to stand a long time on the burnt ore. Another method, by which the sulphuric acid is transferred to the alumina, is the peroxidation of the protoxide in the sulphate of iron; acid is by this means set free and begins to act on the alumina.

The protosulphate of iron being formed, it is removed by boiling down the liquor until the protosulphate of iron crystallises out, at the same time the solution becoming saturated with the aluminous salt. The sulphate of iron is soluble in 0·3 of hot water, the alum in 0·06. The liquid around the crystals on the remaining mother liquor contains iron also; this is washed off by adding pure liquors.

The presence of lime or magnesia in the ores is, of course, a means of abstracting acid, preventing the alumina being dissolved, and even precipitating it when dissolved.

Knapp says that at Salzweiler, near Duttweiler, in Rhenish Prussia, the roasting of the ore takes place in the pit or mine. The stratum of brown coal which lies under it, having been accidentally set fire to in 1660, has smouldered till the present time without intermission.

When the ores are roasted, one half of the sulphur is freed and sent into the mass or escapes as sulphurous acid; and the remaining, protosulphuret of iron, is afterwards converted into green vitriol.

When the calcined mineral becomes thoroughly cold, we may proceed to the lixiviation. But as, from the first construction of the piles or beds till their complete calcination, many weeks, or even months, may elapse, care ought to be taken to provide a sufficient number or extent of them, so as to have an adequate supply of material for carrying on the lixiviating and crystallising processes during the course of the year, or at least during the severity of the winter season, when the calcination may be suspended, and the lixiviation becomes unsatisfactory. The beds are known to be sufficiently decomposed by the efflorescence of the salt which appears upon the stones, from the strong aluminous taste of the ashes, and from the appropriate chemical test of lixiviating an aliquot average portion of the mass, and seeing how much alum it will yield with solution sulphate of potash or chloride of potassium.

Digitized by Google

2. *The Lixiviation.* — The lixiviation is best performed in stone-built cisterns; those of wood, however strong at first, are soon decomposed, and need repairs. They ought to be erected in the neighbourhood of the calcining heaps, to save the labour of transport, and so arranged that the solutions from the higher cisterns may spontaneously flow into the lower. In this point of view, a sloping terrace is the best situation for an alum work. In the lowest part of this terrace, and in the neighbourhood of the boiling-house, there ought to be two or more large tanks, for holding the crude lixivium, and they should be protected from the rain by a proper shed. Upon a somewhat higher level the cisterns of the clear lixivium may be placed. Into the highest range of cisterns the calcined mineral is to be put, taking care to lay the largest lumps at the bottom, and to cover them with lighter ashes. A sufficient quantity of water is now to be run over it, and allowed to rest for some time. The lixivium may then be drawn off, by a stopcock connected with a pipe at the bottom of the cistern, and run into another cistern at a somewhat lower level. Fresh water must now be poured on the partly exhausted schist, and allowed to remain for a sufficient time. This lixivium, being weak, should be run off into a separate tank. In some cases a third addition of fresh water may be requisite, and the weak lixivium which is drawn off may be reserved for a fresh portion of calcined mineral. In order to save evaporation, it is always requisite to strengthen weak leys by employing them instead of water for fresh portions of calcined schist. Upon the ingenious disposition and form of these lixiviating cisterns, much of the economy and success of an alum work depends. The hydrometer should be always used to determine the degree of concentration which the solutions acquire.

The lixiviated stone, being thus exhausted of its soluble ingredients, is to be removed from the cisterns, and piled up in a heap in any convenient place, where it may be left, either spontaneously to decompose, or, after drying, subjected to another calcination.

After calcining and washing the Campsie ores, the residue had the following composition: —

Silica	38·40
Alumina	12·70
Peroxide of iron	20·80
Oxide of manganese	traces
Lime	2·07
Magnesia	2·00
Potash	1·00
Sulphuric acid	10·76
Water	12·27
	100·00

It is, therefore, very far from being a complete process; but it is not considered profitable to remove the whole of the alumina. In some places the exhausted ore is burnt a second time with fresh ore, as at Campsie, but we are not told the estimated exhaustion.

The density of the solution may be brought, upon an average, up to the specific gravity of from 1·09 to 1·15. The latter density may always be obtained by pumping up the weaker solutions upon fresh calcined *mine*. This strong liquor is then drawn off, when the sulphate of lime, the oxide of iron, and the earths are deposited. It is of advantage to leave the liquor exposed to air for some time, whereby the green vitriol may pass into a persulphate of iron with the deposition of some oxide, when the acid will act better on the clay present, so as to increase the quantity of sulphate of alumina. The manufacture of alum is the more imperfect, as the quantity of sulphate of iron left undecomposed is greater, and therefore every expedient ought to be tried to convert the sulphate of iron into sulphate of alumina.

3. *The Evaporation of the Schist Lixivium.* — As the aluminous liquors, however well settled at first, are apt, on the great scale, to deposit earthy matters in the course of their concentration by heat, they are best evaporated by a surface fire, such as that employed at Hurlet and Campsie. A water-tight stone-cistern must be built, having a layer of well-rammed clay behind the flags or tiles which line its bottom and sides. The cistern may be 4 or 6 feet wide, 2 or 3 feet deep, and 30 or 40 feet long, and it is covered in by an arch of stone or brickwork. At one extremity of this tunnel, or covered canal, a fire-grate is set, and at the other a lofty chimney is erected. The cistern being filled to the brim with the alum ley, a strong fire is kindled in the reverberatory grate, and the flame and hot air are forced to sweep along the surface of the liquor, so as to keep it in constant ebullition, and to carry off the aqueous parts in vapour. The soot which is condensed in the process falls to the bottom, and leaves

Digitized by Google

the body of the liquor clear. As the concentration goes on, more of the rough lixivium is run in from the settling cistern, placed on a somewhat higher level, till the whole gets charged with a clear liquor of a specific gravity sufficiently high for transferring into the proper lead boilers.

At Whitby, the lead pans are 10 feet long, 4 feet 9 inches wide, 2 feet 2 inches deep at the one end, and 2 feet 8 inches deep at the other. This increase of depth and corresponding slope facilitates the decantation of the concentrated lixivium by means of a syphon applied at the lower end. The bottom of the pan is supported by a series of parallel iron bars placed very near each other. In these lead pans the liquor is concentrated, at a brisk boiling heat, by means of the flame of a flue beneath them. Every morning the pans are emptied into a settling cistern of stone or lead. The specific gravity of the liquor should be about 1·4 or 1·5, being a saturated solution of the saline matters present. The proper degree of density must vary, however, with different kinds of lixivia, and according to the different views of the manufacturer. For a liquor which consists of two parts of sulphate of alumina, and one part of sulphate of iron, a specific gravity of 1·25 may be sufficient; but for a solution which contains two parts of sulphate of iron to one of sulphate of alumina, so that the green vitriol must be withdrawn first of all by crystallisation, a specific gravity of 1·4 may be requisite.

The construction of an evaporating furnace well adapted to the concentration of aluminous and other crude lixivia is described under SODA. The liquor basin may be made of tiles or flags puddled in clay, and secured at the seams with a good *hydraulic* cement. A mortar made of quicklime mixed with the exhausted schist in powder, and iron turnings, is said to answer well for this purpose. Sometimes over the reverberatory furnace a flat pan is laid, instead of the arched top, into which the crude liquor is put for neutralisation and partial concentration. In Germany, such a pan is made of copper, because iron would waste too fast, and lead would be apt to melt. From this preparation-basin the under evaporating trough is gradually supplied with hot liquor. At one side of this lower trough, there is sometimes a door, through which the sediment may be raked out as it accumulates upon the bottom. Such a contrivance is convenient for this mode of evaporation, and it permits, also, any repairs to be readily made; but, indeed, an apparatus of this kind, well mounted at first, will serve for many years.

In the course of the final concentration of the liquors, it is customary to add some of the mother waters of a former process, the quantity of which must be regulated by a proper analysis and knowledge of their contents. If these mother waters contain much free sulphuric acid, they may prove useful in dissolving a portion of the alumina of the sediment which is always present in greater or less quantity.

4. *The Precipitation of the Alum by adding Alkaline Salts.*—As a general rule, it is most advantageous to separate, first of all, from the concentrated clear liquors, the alum in the state of powder or small crystals, by addition of the proper alkaline matters, and to leave the mingled foreign salts, such as the sulphate of iron or magnesia, in solution, instead of trying to abstract those salts by a previous crystallisation. In this way we not only simplify and accelerate the manufacture of alum, and leave the mother waters to be worked up at any convenient season, but we also avoid the risk of withdrawing any of the sulphate of alumina with the sulphate of iron or magnesia. On this account, the concentration of the liquor ought not to be pushed so far as that, when it gets cold, it should throw out crystals, but merely to the verge of this point. This density may be determined by suitable experiments. The powder of alum is also called *flour*.

The clear liquor should now be run off into the precipitation cistern, and have the sulphate of potash or chloride of potassium, or impure sulphate or carbonate of ammonia, added to it. The sulphate of potash, which is the most direct, forms 18·34 parts out of 100 of crystallised alum; and therefore that quantity, or an equivalent in chloride of potassium, or other potash, or ammoniacal salts, must be introduced into the aluminous liquor. Since sulphate of potash takes 10 parts of cold water to dissolve it, but is much more soluble in boiling water, and since the precipitation of alum is more abundant the more concentrated the mingled solutions are it would be prudent to add the sulphate solution as hot as may be convenient: but, as chloride of potassium is fully three times more soluble in cold water, it is to be preferred as a precipitant, when it can be procured at a cheap rate. It has, also, the advantage of decomposing the sulphate of iron present into a chloride, a salt very difficult of crystallisation, and, therefore, less apt to contaminate the crystals of alum. The quantity of alkaline salts requisite to precipitate the alum, in a granular powder, from the lixivium, depends on their richness in potash or ammonia, on the one hand, and on the richness of the liquors in sulphate of alumina on the other; and this must be ascertained, for each large quantity of product, by a preliminary experiment in a

Digitized by Google

precipitation glass. Here, an aliquot measure of the aluminous liquor being taken, the liquid precipitant must be added in successive portions, as long as it causes any cloud, when the quantity added will be indicated by the graduation of the vessel. A very exact approximation is not practicable upon the great scale; but, as the mother waters are afterwards mixed together in one cistern, any excess of the precipitant at one time is corrected by excess of aluminous sulphate at another, and the resulting alum meal is collected at the bottom. When the precipitated saline powder is thoroughly settled and cooled, the supernatant mother water must be drawn off by a pump, or rather a syphon or stopcock, into a lower cistern. The more completely this drainage is effected, the more easily and completely will the alum be purified.

100 parts of alum are formed from the sulphate of alumina liquor,
by 18·32 of sulphate of potash,
„ 13·86 of sulphate of ammonia,
or 15·69 of chloride of potassium.

Sulphate of ammonia is soluble in 1 of hot and 2 of cold water; sulphate of potash in nearly 10, and chloride of potassium in 3, of water of ordinary temperature; alum, in 13 parts of water. A portion of the alum formed will remain in solution; this will depend on the quantity of liquid; the rest falls as a powder.

This mother liquor has generally a specific gravity of 1·4 at a medium temperature of the atmosphere, and consists of a saturated solution of sulphate or muriate of black and red oxide of iron, with sulphate of magnesia, in certain localities, and chloride of sodium, when kelp salts have been used as a precipitant, as also a saturated solution of sulphate of alumina. By adding some of it, from time to time, to the fresh lixivia, a portion of that sulphate is converted into alum; but, eventually, the mother water must be evaporated, so as to obtain from it a crop of ferruginous crystals; after which it becomes capable, once more, of giving up its alum to the alkaline precipitants.

When the aluminous lixivia contain a great deal of sulphate of iron, it may be good policy to withdraw a portion of it by crystallisation before precipitating the alum. With this view, the liquors must be evaporated to the density of 1·4, and then run off into crystallising stone cisterns. After the green vitriol has crystallised, the liquor should be pumped back into the evaporating pan, and again brought to the density of 1·4. On adding to it, now, the alkalino-saline precipitants, the alum will fall down from this concentrated solution, in a very minute crystalline powder, easy to wash and purify. But this method requires more vessels and manipulation than the preceding, and should only be had recourse to from necessity; since it compels us to carry on the manufacture of both the valuable alum and the lower priced salts at the same time; moreover, the copperas extracted at first from the schist liquors carries with it, as we have said, a portion of the sulphate of alumina, and acquires thereby a dull aspect; whereas the copperas obtained after the separation of the alum is of a brilliant appearance.

5. *The Washing, or Edulcoration, of the Alum Powder.* — This crystalline pulverulent matter has a brownish colour, from the admixture of the ferruginous liquors; but it may be freed from it by washing with very cold water, which dissolves not more than one-eighteenth of its weight of alum. After stirring the powder and the water well together, the former must be allowed to settle, and then the washing must be drawn off. A second washing will render the alum nearly pure. The less water is employed and the more effectually it is drained off, the more complete is the process. The second water may be used in the first washing of another portion of alum powder, in the place of pure water. These washings may be added to the schist lixivia. This powder is now extensively sold without further manipulation.

6. *The Crystallisation.* — The washed alum is put into a lead pan, with just enough water to dissolve it at a boiling heat; fire is applied, and the solution is promoted by stirring. Whenever it is dissolved in a saturated state, it is run off into the crystallising vessels, which are called *roching* casks. These casks are about five feet high, three feet wide at the top, and somewhat wider at the bottom; they are made of very strong staves, nicely fitted to each other, and held together by strong iron hoops, which are driven on *pro tempore*, so that they may be easily knocked off again, in order to take the staves asunder. The concentrated solution, during its slow cooling in these close vessels, forms large regular crystals, which hang down from the top, and project from the sides, while a thick layer or cake lines the whole interior of the cask. At the end of eight or ten days, more or less according to the weather, the hoops and staves are removed, when a cask of apparently solid alum is disclosed to view. The workman now pierces this mass with a pickaxe at the side near the bottom, and allows the mother water of the interior to run off on the sloping

Digitized by Google

stone floor into a proper cistern, whence it is taken and added to another quantity of washed powder to be crystallised with it. The alum is next broken into lumps, exposed in a proper place to dry, and is then put into the finished bing for market. There is sometimes a little insoluble basic alum (subsulphate) left at the bottom of the cask. This, being mixed with the former mother liquors, gets sulphuric acid from them; or, being mixed with a little sulphuric acid, it is equally converted into alum.

Alum Liquors. — In the alum works on the Yorkshire coast, eight different liquors are met with.

1st. "Raw Liquor." The calcined alum shale is steeped in water till the liquor has acquired a specific gravity of 9 or 10 pennyweights, according to the language of the alum-maker.

2nd. "Clarified Liquor." The raw liquor is brought to the boiling point in lead pans, and suffered to stand in a cistern till it has cleared; it is then called clarified liquor. Its gravity is raised to 10 or 11 pennyweights.

3rd. "Concentrated Liquor." Clarified liquor is boiled down to about 20 pennyweights. This is kept merely as a test of the comparative value of the potash salts used by the alum-maker.

4th. "Alum Mother Liquor." The alum pans are fed with clarified liquor, which is boiled down to about 25 or 30 pennyweights, when a proper quantity of potash salt in solution is mixed with it, and the whole run into coolers to crystallise. The liquor pumped from these rough crystals is called "alum mothers."

5th. "Salts Mothers." The alum mothers are boiled down to a crystallising point, and afford a crop of "Rough Epsom," which is a sulphate of magnesia and protoxide of iron.

6th and 7th. "Alum Washings." The rough crystals of alum (No. 4) are washed twice in water, the first washing being about 4 pennyweights, the second about 2½, the difference in gravity being due to mother liquor clinging to the crystals.

8th. "Tun Liquor." The washed crystals are now dissolved in boiling water, and run into the "roching tuns" (wood vessels lined with lead) to crystallise. The mother liquor of the "roch alum" is called "tun liquor:" it is, of course, not quite so pure as a solution of roch alum in water.

The alum-maker's specific-gravity bottle holds 80 pennyweights of water, and by 10 pennyweights he means 10 more than water, or 90.

The numbers on Twaddle's hydrometer, divided by 2·5, give alum-makers' pennyweights.

The alum-maker tests his samples of potash salts comparatively by dissolving equal weights of the different samples in equal measures of alum liquor at 20 pennyweights, heated up to the boiling-point, and weighing the quantity of alum crystals produced on cooling.

For the above information I am indebted to my friend Mr. Maurice Scanlan, who superintended for some time the Mulgrave Alum Works.

He informs me that 6½ tons of the alum rock at the Mulgrave Works, to the north of Whitby, yield, after calcination, &c., one ton of alum.

The price varies with the price of labour and of sulphur. Sulphate of alumina is from 7*l.* to 8*l.* per ton; potash and ammonia alum, 9*l.* per ton; and alum cake, 7*l.* 10*s.* to 8*l.* Their true value consists in the amount of soluble alumina which they contain, and for calico printing also in their freedom from iron.

The alum shales not being very generally found over the country, and nature having interposed certain limits to the amount manufactured and the speed of the process, many attempts have been made to obtain alum and sulphate of alumina.

In 1743, Ambrose Newton wished to economise the manufacture by boiling the scum of the alum works, the muddy deposit in Yorkshire, and adding to the concentrated solution of 45 pennyweights, stale urine, which is ammonia, until the solution became 27 pennyweights. (An old method of hydrometry among alum makers.) The liquor stands "for four days, and strikes out into small allom, and afterwards melted and roached into casks, which stand 14 days, and are taken down and the allom is finished."

Another patent in 1765, by Holme, Cropper, and two Nicholsons, uses stale urine and kelp liquor. They seem to use, by a mistake in names, iron pyrites only for their alum, but no doubt it contained both iron and alumina. They took advantage of the potash, and perhaps also of the soda, of the kelp.

In 1780, Matthew Sanderson patented a plan for making alum by burning the metallic sulphurets, obtaining the sulphuric acid, and uniting it with aluminous earth, —a far-seeing plan, not till long after adopted.

Digitized by Google

In 1794 Lord Dundonald patented a process for "washing aluminous, vitriolic, or pyritous schist or materials with sea water or solutions of salts containing muriate of soda," or mixing muriate of soda with aluminous or vitriolated salts or pyritous substances. He also proposed the use of muriatic acid. It is probable, then, that both a soda- and an ammonia-alum have been manufactured when the whole method was not very clearly understood.

Macquer, Fourcroy, and Vauquelin having discovered the component parts of alum, Chaptal made it from its elements, using clay. He says, "Pure clay upon which the sulphuric acid is digested is dissolved with difficulty." He then says, "I calcine my clays, and reduce them into small pieces, which I spread on the floor of my leaden chambers. The sulphuric acid, which is formed by combustion of a mixture of sulphur and saltpetre, expands itself in the cavity of these chambers, and exists for a certain time in the vaporous form. In this form it has a stronger action than when it has been weakened by the mixture of a quantity of water more or less considerable, so that it seizes the earths, combines with them, causes them to increase in bulk by the effervescence which takes place, and at the end of several days the whole surface exposed to the vapour is converted into alum. Care is taken to stir these earths from time to time, that they may successively present all their surfaces to the action of the acid." "But whatever process may be used to combine the acid with clay, it is necessary to expose the aluminised earths to the air during a greater or less space of time, in order that the combination may be more accurate, and the saturation more complete." This is, in fact, the mode of making the sulphate of alumina. It was then dissolved in water, drawn off clear, to free it from the silica and undissolved matter, mixed with sulphate of potash, evaporated, and crystallised.

The manufacture of the alum from clay seems to have been a good deal used in France. Their method at present, according to Regnault, is as follows:—"They choose clays, such as kaolins, which contain little iron. The clays are then calcined at a low red heat in a furnace; they are ground to powder in a mill, and mixed with half their weight of sulphuric acid of 1·45 specific gravity. The mixture is then heated in another furnace until the sulphuric acid begins to evaporate. It is then taken out, and left to stand for several days." After some time the combination becomes intimate, and the usual method of removing the sulphate of alumina from the insoluble matter is resorted to, and the potash, or ammonia-salt, is added, to convert it into alum.

The most usual method has been to allow it to stand some weeks, or months, until the combination has been effected. This has partially arisen from a supposition of the necessity of giving it as much time as is needful with the shales, as it was not known until lately how completely the acid may decompose the clays.

A patent was obtained in November, 1839, by Mr. William Wiesmann, of Duesburg, for improvements in the manufacture of alum. He subjects potters' clay to a moderate red heat, grinds it, and subjects the powder, in leaden pans, to the action of concentrated sulphuric acid (66° B.), taking care to use excess of clay and a moderate heat. The mixture is to be stirred till it is dry, then treated with boiling water, in order to dissolve the sulphate of alumina formed. So far the process is old and well known. The novelty consists in freeing the saline solution from iron by ferrocyanide of potassium (prussiate of potash). When the iron has been all thrown down in the form of Prussian blue, the liquor is allowed to settle, the supernatant pure sulphate is drawn off, and evaporated till it forms, on cooling, a concrete mass, which may be moulded into the shape of bricks, &c., for the convenience of packing.

This was manufactured at Lee-Moor, near Plympton. Dr. Muspratt's analysis makes it a basic sulphate $= 2Al^2O^3 5SO^3 + 33$ Aq.; and he adds that manufacturers objected to it because it was impossible to judge of its purity by its merely physical appearance. Mohr's analysis gave—

Alumina - - - -	13·91
Sulphuric acid - - -	36·24
Water - - - -	49·60
Sulphate of potash - -	1·50

His mode of removing iron by prussiate of soda is very successful.

By having an excess of clay, Wiesmann intended to have all his acid saturated. He found that he could not dissolve all the alumina by using only its equivalent of acid; he preferred, therefore, to lose the alumina, as in the other processes, from shale and alum-stone.

Hervey's patent of 1839. Clay is dried, ground, and sieved; it is then mixed with sulphuric acid of from 10° to 80 Twad., and from ¼ to an equal quantity of clay, used according to its quality. The mixture is then well stirred; a great ebullition

Digitized by Google

ensues, and after ebullition it is again stirred. This is the formation of the sulphate of alumina, which is washed out, and made into alum in the ordinary way.

In 1842 Mr. Turner patented a method, said to be originally Sprengel's proposal, of extracting the alumina and potash from felspar to make alum. The felspar is heated with sulphate of potash to melting, then carbonate of potash is added. This gives a soluble glass, which, in boiling water, takes up two-thirds of the silica and as much potash as was added to the felspar. This being heated with carbonic acid, gives a gelatinous mass of silica. When dried, the carbonate of potash may be washed out. The insoluble portion of the glass contains the original felspar, minus two-thirds of its silica—a light, porous substance, similar in composition to elaolite. This is boiled with sulphuric acid of 1·2 specific gravity. The intense heat needed has prevented the success of this process.

In 1842 Kagenbusch proposed to cover the schist over with a plastering of clay, or mud, for several months, and wash with water; then to have it burnt in kilns fitted with air holes. In this process turf is used, on which the schist rests. The air holes regulate the combustion, which lasts three days. He uses kelp to obtain the alkali.

In 1850 J. T. Wilson proposed a method of collecting the ammonia from smoke, and using it in making ammonia-alum. What is wanting, he supplements by potash salts, causing a mixed potash- and ammonia-alum to be manufactured.

In 1854 Richardson adds iron pyrites, to increase the amount of sulphur, and, consequently, of sulphuric acid, in the shale; but it does not seem to have been used.

In 1855 Dr. Frankland precipitated the subsulphate of alumina, and added sulphuric acid, thus obtaining the base by a small expenditure of precipitant.

In 1856 J. Metcalf makes a cake similar to the alum-cake described at p. 118; but he uses coarse clay.

In 1856 Henry Pease and Thomas Richardson mix clay with chloride of potassium, or with common salt; they convert both into sulphates; the muriate set free dissolves the alumina, and the chloride of aluminum formed is used as alum.

In 1856 Spilsburg's patent purposed to make alum from kryolite.

The Boghead Cannel-coal ash contains about 30 per cent. of alumina, which it has been proposed to dissolve for making alum; but it has not hitherto been found a convenient material.

Alum Manufacture simplified.—The alum shale, or schist, is the material whence the alumina is obtained: this shale is roasted in heaps in the open air, in order to render it porous and more absorbent of the sulphuric acid. To the roasted shale, sulphuric acid of specific gravity 1·75 is added, by which means sulphate of alumina is formed. In order to wash out from the almost dry mass this sulphate of alumina, and at the same time to supply the equivalent of the sulphate of ammonia necessary to constitute the formation of the double salt of alumina and ammonia, the boiling hot mother liquor of a previous operation is employed; and, as this mother liquor, when removed from the alum crystallisers, contains free sulphuric acid, the ammonia from a still, containing the ammoniacal liquor of the gas works, is distilled into it, and the boiling hot solution of sulphate of ammonia thus formed dissolves out the sulphate of alumina from the shale. The alum liquor thus obtained is of such a specific gravity, that it crystallises without the necessity of having recourse to evaporation, and thus a considerable saving in fuel is effected. In order to obtain ammoniacal salts, such as sulphate and chloride, with the greatest possible economy, a series of two or more—say, for instance, four—cylindrical boilers are employed, each of which is placed at such a distance above the other that the contents of the upper boiler may be drawn off into the one next below it. The uppermost boiler is provided with an exit pipe, and has also a supply pipe, connecting the boiler with a reservoir of ammoniacal gas liquor. Into the lowermost vessel of the series passes a pipe conveying high pressure steam, by means of which the liquor in the boiler soon becomes heated to the boiling point. The vapour of ammonia and water passes off through an exit pipe into the boiler placed next above it in the series, the liquor in which also quickly boils, and vapour of ammonia and water pass off in the same way as before to the next vessel above it, and so throughout the series. By the time the vapour of ammonia passes off from the uppermost boiler, it has been so concentrated that, on passing it into sulphuric or muriatic acid, a concentrated solution of either alkaline salt is obtained, of sufficient specific gravity to crystallise without evaporation, and thus a considerable saving in fuel and time is effected, and the ammoniacal liquor most thoroughly exhausted. Fresh supplies of ammoniacal liquor are constantly furnished to the uppermost vessel from the reservoir; the partially exhausted liquors are run from the higher to the lower vessels in succession, and the exhausted liquors run off to waste, from time to time, from the lowermost vessel of the series.

Alum is made extensively in England and France from an artificial sulphate of

Digitized by Google

alumina. For this purpose clays are chosen as free as possible from carbonate of lime and oxide of iron. They are calcined in a reverberatory furnace, in order to expel the water, to peroxidise the iron, and to render the alumina more easily acted on by the acid. The expulsion of the water renders the clay porous and capable of absorbing the sulphuric acid by capillary attraction. The peroxidation of the iron renders it less soluble in the sulphuric acid; and the silica of the clay, by reacting on the alumina, impairs its aggregation, and makes it more readily attracted by the acid. The clay should therefore be moderately calcined; but not so as to indurate it like pottery ware, for it would then suffer a species of siliceous combination which would make it resist the action of acids. The clay is usually calcined in a reverberatory furnace, the flame of which serves afterwards to heat two evaporating pans and a basin for containing a mixture of the calcined clay and sulphuric acid. As soon as the clay has become friable in the furnace it is taken out, reduced to powder, and passed through a fine sieve. With 100 parts of the pulverised clay, 45 parts of sulphuric acid, of specific gravity 1·45, are well mixed, in a stone basin, arched over with brickwork. The flame and hot air of a reverberatory furnace are made to play along the mixture, in the same way as described for evaporating alum-schist liquors. (See SODA.) The mixture, being stirred from time to time, is, at the end of a few days, to be raked out, and to be set aside in a warm place, for the acid to work on the clay, during six or eight weeks. At the end of this time it must be washed, to extract the sulphate of alumina. With this view, it may be treated like the roasted alum ores above described. If potash-alum is to be formed, this sulphate of alumina is evaporated to the specific gravity of 1·38; but if ammonia-alum, to the specific gravity of only 1·24; because the sulphate of ammonia, being soluble in twice its weight of water, will cause a precipitation of pulverulent alum from a weaker solution of sulphate of alumina than the less soluble sulphate of potash could do.

In preparing alum from clay or shale, it is of infinite importance that so much and no more heat be applied to the clay or shale, in the first instance, as will just expel the water of combination without inducing contraction. A temperature of 600° F. is well adapted to effect this object, provided it be maintained for a sufficient period. When this has been carefully done, the silicate of alumina remaining is easily enough acted upon by sulphuric acid, either slightly diluted or of the ordinary commercial strength. The best form of apparatus is a leaden boiler, divided into two parts by a perforated septum or partition, also in lead; though on a very large scale, brickwork set in clay might be employed. Into one of the compartments the roasted clay or shale should be put, and diluted sulphuric acid being added, the bottom of the other compartment may be exposed to the action of a well-regulated fire, or, what is better, heated by means of steam through the agency of a coil of leaden pipe. In this way a circulation of the fluid takes place throughout the mass of shale; and, as the alumina dissolves, the dense fluid it produces, falling continually towards the bottom of the boiler, is replaced by dilute acid, which, becoming in its turn saturated, falls like the first; and so on in succession, until either the whole of the alumina is taken up, or the acid in great part neutralised. The solution of sulphate of alumina thus obtained is sometimes evaporated to dryness, and sold under the name "concentrated alum;" but more generally it is boiled down until of the specific gravity of about 1·35; then one or other of the carbonates or sulphates of potash or ammonia, or chloride of either base, or a mixture of these, is added to the boiling fluid, and as soon as the solution is complete, the whole is run out into a cooler to crystallise. The rough alum thus made is sometimes purified by a subsequent recrystallisation, after which it is "roched" for the market — a process intended merely to give it the ordinary commercial aspect, but of no real value in a chemical point of view.

The manufacture of alum is now taking an entirely new shape, and the two processes of Mr. Spence and Mr. Pochin threaten to absorb the whole of the manufacture in the north-west.

Mr. Spence, who has a manufactory of ammonia-alum at Manchester, called the Pendleton Alum Works, and another at Goole, in Yorkshire, has now become the largest maker of this substance in the world, as his regular production amounts to upwards of 100 tons per week. In this process, which he has patented, he uses for the production of his sulphate-of-alumina solution the carbonaceous shale of the coal measure. This substance contains from 5 to 10 per cent. of carbonaceous matter, and, when ignited by a small quantity of burning coal, the combustion continues of itself. To insure this the shale is spread into long heaps not exceeding 18 inches in height, and having a brick drain running along each to supply air; in this manner it slowly calcines: this process must be so conducted as not to vitrify the shale. After calcination it is boiled and digested in large leaden pans, heated by fire, with sulphuric acid of 1·4 specific gravity. After 30 to 40 hours of digestion the sulphate of alumina formed is run into another leaden pan, and the boiling vapour from the

Digitized by Google

ammonia liquor of the gas works is passed into it, until so much alumina is combined with the solution as to form ammonia-alum. The solution is then run into shallow leaden coolers and the alum crystallises. It is then purified and washed much in the usual way, only that the process is conducted so as to cause much less labour than at older alum works.

Alum Cake.—This substance owes its value to the amount of sulphate of alumina it contains, and is in fact another means of making soluble alumina accessible. We have already seen the many attempts to obtain alumina from clay, and the tedious nature of the operation of solution in acid, as well as the long after-processes of lixiviation and conversion into sulphate of alumina, or into alum, by reboiling or crystallising. Mr. Pochin, of Manchester, has found a method of removing all the difficulties, both of the first and after processes. He uses very fine china clay, free from iron, heats it in a furnace, mixes it thoroughly with acid, and finds that, when the process is managed carefully, the combination of the alumina and sulphuric acid is not only complete, but so violent that he is obliged to dilute his acid considerably, in order to calm the action. When mixed, it is passed into cisterns with movable sides, where, in a few minutes, it heats violently and boils. The thick liquid gradually becomes thicker, until it is converted into a solid porous mass — the pores being made by the bubbles of steam which rise in the mass, which is not fluid enough to contract to its original volume. The porous mass is perfectly dry, although retaining a large amount of combined water. It retains, of course, all the silica of the original clay, but this is in such fine division that every particle appears homogeneous. The silica gives it a dryness to the touch not easily gained by the sulphate only.

When pure sulphate of alumina is wanted in solution, the silica is allowed to precipitate before using it, but, in many cases, the fine silica is no hindrance; then the solution is made use of at once.

Some quantity of alum has been exported from China, chiefly to India, within a short period. The Chinese use alum very largely in their cements.

The alum mines are in the neighbourhood of Peh-kwan harbour, 2° 9′ 10″ N., 12° 32′ 6″ E. Ten alum-making establishments appear to exist there, and the process, as described in the *North China Mail*, is similar to that employed where, in this country, the alum-shale is used.—R. A. S.

ALUMINA. (Al^2O^3,51·4) This is the only oxide which the metal aluminium forms, and it is assumed to be a sesquioxide on account of its isomorphism with sesquioxide of iron.

The occurrence of alumina in the native state has been before mentioned, and the several minerals will be found described elsewhere.

* The countries to which exported are not given in the returns for these two years.

Digitized by Google

It is obtained in the state of hydrate from common alum (KO,SO^3; $Al^2O^3,3SO^3+24HO$) by adding a solution of ammonia (or better, carbonate of ammonia) to the latter salt and boiling. The precipitate is white, and gelatinous in a high degree, and retains the salts, in the presence of which it has been formed, with remarkable pertinacity, so that it is very difficult to wash.

By drying and igniting this hydrate, the anhydrous alumina is produced; but it may be obtained more readily by heating ammonia-alum (NH^4O,SO^3; $Al^2O^3 3SO^3+24HO$). All the constituents of this salt are volatile, with the exception of the alumina. It is insoluble in water, but soluble both in acids and alkalis. Towards the former it plays the part of a base, producing the ordinary alumina salts; whilst, with the latter, it also enters into combination, but in this case it is an acid, forming a series of compounds which may be called aluminates.

The important application of alumina and its compounds in the arts of dyeing and calico printing depends upon a peculiar attraction which it possesses for organic bodies. This affinity is so strong, that when digested in solutions of vegetable colouring matters the alumina combines with and carries down the colouring matter, removing it entirely from the solution. Pigments thus obtained, which are combinations of alumina with the vegetable colouring matters, are called "*lakes*."

Alumina has not only an affinity for the colouring matters, but at the same time also for the vegetable fibres, cotton, silk, wool, &c.; and hence, if alumina be precipitated upon cloth in the presence of a colouring matter, a most intimate union is effected between the cloth and the colour. Alumina, when employed in this way, is called a "mordant."

Other bodies have a similar attraction for colouring matters, *e.g.* binoxide of tin and sesquioxide of iron: each of these gives its peculiar shade to the colour or combination, alumina changing it least.

Soluble Modification of Alumina.—Mr. Walter Crum* has discovered a peculiar soluble modification of alumina. The biacetate of alumina has been found by Mr. Crum to possess the very curious property of parting with its acetic acid until the whole is expelled, by the long-continued application of heat to a solution of this salt; the alumina remains in the solution in a soluble allotropic condition. Its coagulum with dyewoods is translucent, and entirely different from the opaque cakes formed by ordinary alumina; hence this solution cannot act as a mordant. But this solution of alumina, which is perfectly colourless and transparent, has the alumina separated from it by the slightest causes. A minute quantity of either an acid, an alkali, even of a neutral salt, or of a vegetable colouring matter, effects the change. The precipitated alumina is insoluble in acids, even boiling sulphuric; this shows another allotropic condition. But it is dissolved by caustic alkalis, by which it is restored to its common state.—H. M. W.

ALUMINA, ACETATE OF. The acetates of alumina are extensively used in the arts on account of the property which they possess of being readily decomposed with deposition of their alumina on the fibre of cloth; hence they are used as mordants, in the manner described under CALICO PRINTING; and sometimes in dyeing they are mixed with the solution of a colouring matter; in this the textile fabric is immersed, whilst, on heating, the alumina is precipitated upon the fabric, which, in consequence of its affinities before alluded to, carries down the colouring matter with it, and fixes it on the cloth.

The acetate of alumina thus employed is obtained by treating sulphate of alumina with neutral acetate of lead, and filtering off the solution from the precipitate of sulphate of lead. Acetate of lime is also used; but the sulphate in this case does not leave the solution so clear or so rapidly.

According to Mr. Walter Crum*, the solution resulting from the decomposition of sulphate of alumina (Al^2O^3, $3SO^3$) by monobasic acetate of lead contains the salt $Al^2O^3,2C^4H^3O^3$ (biacetate of alumina), together with one equivalent of free acetic acid, the compound $Al^2O^3,3C^4H^3O^3$ not appearing to exist. By evaporating this solution at low temperatures, *e.g.* in a very thin layer of fluid below 38°C. (100°F.), Crum obtained a fixed residue completely soluble in water, the composition of which, in the dry state, approached Al^2O^3, $2C^4H^3O^3+4HO$.—H. M. W.

ALUMINA, NITRATE OF. According to Ordway ("Siliman's Journal," iv. 30), a concentrated acid solution of alumina in nitric acid deposits rhombic crystals containing Al^2O^3, $3NO^5+18HO$. By the action of this salt on hydrate of alumina basic salts are also formed.—H. M. W.

ALUMINA, SILICATES OF. Silicate of alumina is the chief constituent of common clay (*which see*); it occurs also associated with the silicates of iron, mag-

* Chemical Society's Quarterly Journal, vi. 216.

nesia, lime, and the alkalis in a great variety of minerals, which will be found described elsewhere. The most interesting of these are the felspars and the zeolites. See CLAY.

Of course, being present in clay, silicate of alumina is the essential constituent of porcelain and earthenware. See EARTHENWARE and PORCELAIN.—H. M. W.

ALUMINA, SULPHATE OF. The neutral sulphate of alumina, Al^2O^3, $3SO^3 + 18HO$, which is obtained by dissolving alumina in sulphuric acid, crystallises in needles and plates; but sulphuric acid and alumina combine in other proportions, *e.g.* a salt of the formula Al^2O^3, $3SO^3 + Al^2O^3$ was obtained by Mons, and the solution of this salt, when largely diluted with water, splits into the neutral sulphate and an insoluble powder containing Al^2O^3, $3SO^3 + 2Al^2O^3 + 9HO$. This subsalt forms the mineral *aluminite*, found near Newhaven, and was found by Humboldt in the schists of the Andes.

The sulphate of alumina is now extensively used in the arts instead of alum, under the name of "concentrated alum." For most of the purposes for which alum is employed, the sulphate of potash is an unnecessary constituent, being only added in order to facilitate the purification of the compound from iron; for in consequence of the ready crystallisability of alum, this salt is easily purified. Nevertheless, Wiesmann has succeeded in removing the iron from the crude solution of sulphate of alumina obtained by treating clay with sulphuric acid, by adding ferrocyanide of potassium, which throws down the iron as Prussian blue; the solution, when evaporated to dryness, is found to consist of sulphate of alumina, containing about 7 per cent. of potash alum. 1500 tons of this article were produced at Newcastle-on-Tyne alone in the year 1854. See also ALUM.—H. M. W.

ALUMINIUM. (*Sym.* Al., *equiv.* 13·7.) The name Aluminium is derived from the Latin *alumen*, for alum, of which salt this metal is the notable constituent.

Aluminium, though never found in the free state, occurs extensively diffused in nature in alumina and certain of its salts, especially the silicates.

The native varieties of *anhydrous* alumina are, the sapphire, ruby, and corundum (*which see*), whilst the hydrate occurs in nature in the minerals, diaspore and gibbsite. But the chief quantity of aluminium is found in the endless varieties of the mineral silicates of alumina with other bases, such as the felspars, micas, many kinds of clay, the zeolites, &c.

Alumina was first decomposed by Davy, who discovered the metal soon after decomposing the other earths and alkalis; but he never seems to have obtained it without some mixture of potassium. It is evident, however, that the earth was completely reduced to the metallic state by him.

Wöhler obtained aluminium pure in 1827 * by the reduction of the chloride of aluminum in the form of a grey powder. Later (1845) †, he succeeded by the same process in obtaining it in globules, which he describes as tin white, tolerably malleable and ductile, not materially oxidised by exposure to the air, of a specific gravity of 2·5, but, when hammered, of 2·67; unacted upon by water at the common temperature, but slowly disengaging hydrogen from water at the boiling point.

In 1854 ‡ Deville's first experiments on the preparation and properties of aluminium were published. The method he adopted for the liberation of the metal was essentially the same as that originally employed by Wöhler. But, by dint of improvements in the details of the process, he succeeded in procuring the metal in larger globules, which were silver white, having a fusing point nearly approaching that of silver, which were unoxidised when exposed to the air, even in a fused state, and remaining bright *even in boiling water*, unattacked by either dilute or concentrated nitric or sulphuric acid in the cold; but dissolved by hydrochloric acid with evolution of hydrogen.

Œrsted was undoubtedly the first to prepare the chloride of aluminium §, and it is even stated that he also procured the metal by the following method: "Pure alumina intimately mixed with powdered charcoal was introduced into a porcelain tube; through this, when strongly heated, a stream of chlorine was directed, and the chloride of aluminium formed was collected in a separate vessel. By mixing this compound with an amalgam of potassium, containing a large proportion of the latter body, and immediately heating the mixture, chloride of potassium was found, and the aluminium combined with the mercury. This, on being distilled out of contact with the air, gave off the mercury, whilst aluminium remained in the form of a metallic button, closely resembling tin." ‖

Deville's researches raised the hope that the metal might be obtained in sufficient quantity to become of high technical importance, since it was probable that the

chloride of aluminium might be decomposed by cheaper metals at a higher temperature; and he obtained a grant from the Emperor of the French for the purpose of prosecuting his investigations on a sufficient scale.

Bunsen also showed in 1854* that aluminium could be obtained in reguline masses by submitting the double chloride of aluminium and sodium or potassium to electrolysis in a fused state.

By fusing the chloride of aluminium (obtained by the process which will be found described under the head of the chloride) with an equal equivalent of common salt, he obtained a double chloride, which fused below 200° C. (360° F.), and from which the metal is readily reduced by the same electrolytic process previously employed by Bunsen in the case of magnesium (*which see*).

Bunsen pointed out that the discrepancy existing in the properties of the metal in the two states, as obtained respectively by Wöhler and Deville, arose from its physical condition; for Bunsen found that it was only the massive metal which possessed the properties ascribed to it by Deville, that in fact the pulverulent modification does decompose water at 100° C., as stated by Wöhler.

Almost at the same time Deville published the results of his experiments upon the production of aluminium on a larger scale.† He quite gave up the hope of succeeding in effecting the reduction of the chlorides by any of the common metals. He adhered to Wöhler's and Bunsen's methods, carrying them out on a larger scale, with modifications and improvements in the details, which enabled him to obtain the metal in such quantities, and thus to study its properties with so much success, as to suggest numerous applications, the probability of which never entered the minds of the original discoverers. Very great credit is therefore due to M. Deville, although it is the practice amongst the German chemists to detract from, or even deny, his merit.

The following is the method described by M. Deville for the preparation of this interesting metal.

Having obtained the chloride of aluminium, he introduces into a wide glass (or porcelain) tube 200 or 300 grammes of this salt between two plugs of asbestos (or in a boat of porcelain or even copper), allows a current of hydrogen to pass from the generator through a desiccating bottle containing sulphuric acid and tubes containing chloride of calcium, and finally through the tube containing the chloride; at the same time applying a gentle heat to the chloride, to drive off any free hydrochloric acid which might be formed by the action of the air upon it. He now introduces at the other extremity of the tube a porcelain boat containing sodium; and when the sodium is fused the chloride of aluminium is heated, until its vapour comes in contact with the fused sodium. A powerful reaction ensues, considerable heat is evolved, and by continuing to pass the vapour of the chloride over the sodium until the latter is all consumed, a mass is obtained in the boat of the double chloride of aluminium and sodium ($NaCl, Al^2 Cl^3$), in which globules of the newly reduced metal are suspended. It is allowed to cool in the hydrogen, and then the mass is treated with water, in which the double chloride is soluble, the globules of metal being unacted upon.

These small globules are finally fused together in a porcelain crucible, by heating them strongly under the fused double chloride of aluminium and sodium, or even under common salt.

This process, which succeeds without much difficulty on a small scale, is performed far more successfully as a manufacturing operation. Two cast-iron cylinders are now employed instead of the glass or porcelain tube, the anterior one of which contains the chloride of aluminium, whilst in the posterior one is placed the sodium in a tray, about 10 lbs. being employed in a single operation. A smaller iron cylinder intermediate between the two former is filled with scraps of iron, which serve to separate iron from the vapour of chloride of aluminium, by converting the perchloride of iron into the much less volatile protochloride. They also separate free hydrochloric acid and chloride of sulphur.

During the progress of the operation the connecting tube is kept at a temperature of about 400° to 600° F.; but both the cylinders are but very gently heated, since the chloride of aluminium is volatile at a comparatively low temperature, and the reaction between it and the sodium when once commenced generates so much heat that frequently no external aid is required.

Preparation of Aluminium by Electrolysis. — Mr. Gore has succeeded in obtaining plates of copper coated with aluminium by the electrolysis of solutions of chloride of aluminium, acetate of alumina, and even common alum ‡; but the unalloyed metal cannot be obtained by the electrolysis of solutions. Deville, however, produced it in considerable quantities by the method originally suggested by Bunsen, viz. by the

Digitized by Google

electrolysis of the fused double chloride of aluminium and sodium ($Na\,F, Al^2\,F^3$); but since this process is far more troublesome and expensive than its reduction by sodium, it has been altogether superseded.

Preparation of Aluminium from Kryolite.—So early as March 30, 1855, a specimen of aluminium was exhibited at one of the Friday evening meetings of the Royal Institution, which had been obtained in Dr. Percy's laboratory by Mr. Allan Dick, by a process entirely different from that of Deville, which promised, on account of its great simplicity, to supersede all others.* It consisted in heating small pieces of sodium, placed in alternate layers with powdered kryolite, a mineral now found in considerable abundance in Greenland, which is a double fluoride of aluminium and sodium, analogous to the double chloride of aluminium and sodium, its formula being $Na\,F, Al^2\,F^3$. The process has the advantage that one of the materials is furnished ready formed by nature.

The experiment was only performed on a small scale by Mr. Dick in a platinum crucible lined with magnesia; the small globules of metal, which were obtained at the bottom of the mass of fused salt, being subsequently fused together under chloride of potassium or common salt.

Before the description of these experiments was published, M. Rose, of Berlin, published a paper in September, 1855, on the same subject.† In Rose's experiments he employed cast-iron crucibles, in which was heated ten parts of a mixture of equal weights of kryolite and chloride of potassium with 2 parts of sodium. The aluminium was obtained in small globules, which were fused together under chloride of potassium, as in Mr. Dicks' experiments.

Rose experienced a slight loss of aluminium by fusion under chloride of potassium, and found it more advantageous to perform this fusion under a stratum of the double chloride of aluminium and sodium, as Deville had done.

He never succeeded in extracting the whole quantity of aluminium present in the kryolite (13 per cent.), chiefly on account of the ready oxidisability of the metal when existing in a very finely divided state, as some of it invariably does.

It does not appear that any attempt has since been made to obtain aluminium on the large scale from kryolite, probably from the supply of the mineral not proving so abundant as was at one time anticipated.

In all the processes which have been found practicable on any considerable scale, for the manufacture of aluminium, the powerful affinities of sodium are employed for the purpose of eliminating it from its compounds. The problem of the diminution of the price of aluminium therefore resolves itself into the improvement of the methods for procuring sodium, so as to diminish the cost of the latter metal. M. Deville's attention was therefore directed, in the early steps of the inquiry, to this point; and very considerable improvements have been made by him, which will be found fully described under the head of SODIUM.

Deville‡ has since suggested the employment at once of the double salt of chloride of aluminium and chloride of sodium ($NaCl, Al^2\,Cl^3$), instead of the simple chloride of aluminium, so as to obtain the metal by means of sodium. He uses 400 parts of this double salt, 200 of common salt, 200 of fluor spar, and 75 to 80 of sodium. The above-mentioned salts are dried, powdered, and mixed together; then with these the sodium, in small pieces, is mixed, and the whole heated in a crucible under a layer of common salt. After the reaction is complete, the heat is raised so as to promote the separation of the aluminium in the form of a button. It was found, however, that kryolite was, with advantage, substituted for the fluor spar.

C. Brunner§ employs artificially prepared fluoride of aluminium; but this method cannot offer any advantage over the employment of the chloride, which is cheaper, or the kryolite, which nature affords.

The following remarks on the manufacture of Aluminium are from the pen of Mr. Isaac Lowthian Bell of Newcastle, at whose works at Washington this metal is now produced, this indeed being the only manufactory in this couuntry:—

"Upon the introduction of its manufacture at Washington, three-and-a-half years ago, the source of the alumina was the ordinary ammonia-alum of commerce—a nearly pure sulphate of alumina and ammonia. Exposure to heat drove off the water, sulphuric acid, and ammonia, leaving the alumina behind. This was converted into the double chloride of aluminium and sodium, by the process described by the French chemist, and practised in France, and the double chloride was subsequently decomposed by fusion with sodium. Faint, however, as the traces might be of impurity in the alum itself, they to a great extent, if not entirely (being of a fixed character when exposed to heat), were to be found in the alumina. From the alumina, by the action of chlorine on a heated mixture consisting of this earth,

common salt, and charcoal, these impurities, or a large proportion thereof, found their way into the sublimed double chloride; and once there, it is unnecessary to say that, under the influence of the sodium in the process of reduction, any silica, iron, or phosphorus found their way into the aluminium sought to be obtained. Now, it happens that the presence of foreign matters, in a degree so small as almost to be infinitesimal, interferes so largely with the colour as well as with the malleability of the aluminium, that the use of any substance containing them is of a fatal character. Nor is this all, for the nature of that compound which hitherto has constituted the most important application of this metal—aluminium bronze—is so completely changed by using aluminium containing the impurities referred to, that it ceases to possess any of those properties which render it valuable. As an example of the amount of interference exercised by very minute quantities of impurity, it is perhaps worthy of notice that very few varieties of copper have been found susceptible of being employed for the manufacture of aluminium bronze; and hitherto we have not at Washington, nor have they in France, been able to establish in what the difference consists, between copper fit for the production of aluminium bronze, and that which is usually unsuitable for the purpose. These considerations have led us, both here and in France, to adopt the use of another raw material for the production of aluminium, which either does not contain the impurities referred to as so prejudicial, or contains them in such a form as to admit of their easy separation. This material is Bauxite, so called from the name of the locality where it is found in France. The Bauxite is ground and mixed with the ordinary soda-ash of commerce, and then heated in a furnace. The soda combines with the alumina, and the aluminate of soda so formed is separated from the insoluble portions—viz., peroxide of iron, silico-aluminate of soda, &c.—by lixiviation. Muriatic acid or carbonic acid is then added to the solution, which throws down pure alumina. The remainder of the process is precisely that which is described by Mons. St. Claire Deville. The alumina is mixed with common salt and charcoal, made into balls the size of an orange and dried. These balls are placed in vertical earthen retorts, kept at a red heat, and through the heated contents chlorine gas is passed. The elements of the earth, under the joint influence of carbon and chlorine at that temperature, are separated, the carbon taking the oxygen and the chlorine the aluminium. The latter substance accompanied by chloride of sodium (common salt) sublimes over, and is collected as a double chloride of aluminium and sodium. Sodium,—being required to effect the decomposition of this compound,—is thus prepared. In small iron retorts kept at as high a temperature as iron can bear, a mixture of soda (carbonate of soda) and carbonaceous matter with a little ground chalk is placed. The metallic base of the alkali distils over, and is collected in coal oil. A portion of the double chloride of aluminium and sodium, and the metallic sodium, along with fluxes, is exposed to a full red heat in a reverberating furnace. The sodium seizes the chlorine combined with the aluminium, and thus liberates the lattter metal, which falls to the bottom of the fixed mass. Aluminium is used in sufficient quantity to keep the only work in England—viz., that at Washington—pretty actively employed. As a substance for works of art, when whitened by means of hydrofluoric and phosphoric acid, it appears well adapted, as it runs into the most complicated patterns, and has the advantage of preserving its colour, from the absence of all tendency to unite with sulphur, or to become affected by sulphuretted hydrogen, as happens with silver." Aluminium has been used in the manufacture of weights and scale-beams for chemists, and for opera and field-glasses, for which purposes it is exceedingly valuable, by reason of its lightness and its not being liable to tarnish. A greatly increased activity has been given to the manufacture of aluminium by its use in the manufacture of aluminium-bronze—a compound of exceeding beauty, so much like gold that it can scarcely be distinguished from that precious metal.

Properties.—The metal is white, but with a bluish tinge, and even when pure has a lustre far inferior to silver.

Specific gravity, 2·56, and when hammered, 2·67.

Conducts electricity eight times better than iron, and is feebly magnetic.

Its fusing-point is between the melting-points of zinc and silver.

By electrolysis it is obtained in forms which Deville believes to be regular octahedra; but Rose, who has also occasionally obtained aluminium in a crystalline state (from kryolite), denies that they belong to the regular system.

When pure, it is unoxidised even in moist air; but most of the commercial specimens (probably from impurities present in the metal) become covered with a bluish-grey tarnish.

It is unaffected by cold or boiling water; even steam at a red heat is but slowly decomposed by it.

It is not acted upon by cold nitric acid, and only very slowly dissolved even by the

Digitized by Google

boiling acid; scarcely attacked by dilute sulphuric acid, but readily dissolved by hydrochloric acid, with evolution of hydrogen.

Sulphuretted hydrogen and sulphides have no action upon it; and it is not even attacked by fused hydrated alkalis. Professor Wheatstone* has shown that in the voltaic series, aluminium, although having so small an atomic number, and so low a specific gravity, is more electro-negative than zinc; but it is positive to cadmium, tin, lead, iron, copper, and platinum.

Impurities in Aluminium.—Many of the discrepancies in the properties of aluminium, as obtained by different experimenters, are due to the impurities which are present in it.

If the naphtha be not carefully removed from the sodium, the aluminium is liable to contain carbon.

Frequently, in preparing aluminium, by the action of the chloride on sodium, by Deville's original process, copper boats have been used for holding the sodium; in this case the metal becomes contaminated, not only with copper, but also with any other metals which may be present in the copper—*e.g.* Salm-Horstmar† found copper in the aluminium sold in Paris, and Erdmann detected zinc‡; and in every case the metal is very liable to become mixed with silicon, either from the earthenware tubes, boats, or crucibles, hence Salvetat found, even in the aluminium prepared by Deville himself, 2·87 per cent. of silicon, 2·40 of iron, 6·38 of copper, and traces of lead.

The following analysis of commercial aluminium was communicated to the British Association, at its meeting in 1857, by Professor Mallet.

Alloys of Aluminium.—Very small quantities of other metals suffice to destroy the malleability and ductility of aluminium. An alloy containing only $\frac{1}{20}$th of iron or copper cannot be worked, and the presence of $\frac{1}{10}$th copper renders it as brittle as glass. Silver and gold produce brittleness in a less degree. An alloy of 5 parts of silver with 100 of aluminium, is capable of being worked like the pure metal, but it is harder, and therefore susceptible of a finer polish; whilst the alloy, containing 10 per cent. of gold, is softer, but, nevertheless, not so malleable as the pure metal. The presence of even $\frac{1}{1000}$th part of bismuth renders aluminium brittle in a high degree.

These statements by Tissier§, however, require confirmation; for Debray states that aluminium remains malleable and tough when containing as much as 8 per cent. of iron, or 10 per cent. of copper, but that a larger quantity of either of these metals renders it brittle.

It is curious that only 3 per cent. of silver are sufficient to give aluminium *the brilliance and colour of pure silver, over which the alloy has the great advantage* of not being blackened by sulphuretted hydrogen.

On the other hand, small quantities of aluminium combined with other metals change their properties in a remarkable manner. Thus copper alloyed with only $\frac{1}{10}$th of its weight of aluminium has the colour and brilliance of gold, and is still very malleable (*Tissier*); and when the aluminium amounts only to $\frac{1}{5}$th (*i.e.* 20 per cent.) the alloy is quite white (*Debray*). See ALUMINIUM BRONZE.

An alloy of 90 parts of copper and 10 of aluminium is harder than common bronze, and is capable of being worked at high temperatures easier than the best varieties of iron. Larger quantities of aluminium render the metal harder and brittle.—*Debray.*‖

An alloy of 100 parts of silver with 5 of aluminium is as hard as the alloy employed in the silver coinage, although the other properties of the silver remain unchanged (*Tissier*). Similar alloys have likewise been prepared by Dr. Percy.¶

Messrs. Calvert and Johnson describe** an alloy of 25 parts aluminium to 75 of iron, which has the valuable property of *not oxidising by exposure to moist air.*

Uses of Aluminium.—No very important application of aluminium has yet been made, although, at the time M. Deville's experiments were commenced, sanguine hopes were entertained that aluminium might be produced at a price sufficiently low to admit of its practical application on a large scale, these anticipations have

not been realised; and as yet, on account chiefly of its high price,* the applications which have been made of this interesting metal are but few.

Its low specific gravity, combined with sufficient tenacity, recommends it for many interesting uses. The fractional weights used by chemists, which are made of platinum, are so extremely small that they are constantly being lost; their much greater volume in aluminium renders this metal peculiarly suitable. In the construction of the beams of balances, strength combined with lightness are desiderata; and M. Deville has had very beautiful balance-beams made of this metal; but at present its high price has prevented their extensive adoption.

These same qualities render this metal suitable for the construction of helmets and other armour; but at present these are but curiosities, and are likely to remain so, unless some cheaper method of eliminating the metal than by the agency of sodium be discovered.

Probably one of the most interesting of the applications of aluminium (at least in a scientific point of view) that has been made, is the recent one by Deville and Wöhler, of employing it in the production of crystalline allotropic modifications of certain other elements hitherto unknown in that state—*e.g.* boron, silicon, and titanium (*which see*). It depends upon the fact that these elements, in the amorphous state, dissolved in fused aluminium, and, on cooling the molten solution, they slowly separate from the aluminium in the crystalline state. Aluminium may be gilded by being dipped into a solution of the hyposulphite of gold after it has been well cleaned by the successive use of potash, nitric acid, and water Aluminium is soldered with difficulty. The most successful method is to coat the aluminium with copper by the electrotype process, after which soldering can be effected in the usual way.

Our first importation of aluminium was in 1856, to the value of 35*l.*: in 1863 we imported 29,140 lbs., valued at 69,779*l.*—H. M. W.

ALUMINIUM BRONZE. This alloy was a discovery of Dr. John Percy, F.R.S., and it appears to be a true chemical compound. Mr. I. L. Bell, who manufactures this beautiful metallic compound on a large scale, thus describes its manufacture:—"Copper is melted in a plumbago crucible, and, after being removed from the furnace, the solid aluminium is added. The union of the two metals is attended with such an increase of temperature that the whole becomes white hot, and unless the crucible containing the mixture is of a refractory material, it is fused by the intensity of the heat. A vessel which has resisted a heat sufficient to effect the fusion of copper has been melted when the aluminium has been added."

Mr. Gordon has shown that the amount of tension which aluminium wire was capable of resisting will be found to be between that of the best iron and the best steel wire.

The value of aluminium bronze will be gathered from the following statement of results obtained by Lieut.-Colonel A Strange, F.R.A.S., and communicated by him to the Astronomical Society. Lieut.-Colonel Strange recommended this metal as a valuable material for the construction of astronomical and other philosophical instruments. Regarding the most important qualities as—1. Tensile strength 2. Resistance to compression, 3. Malleability, 4. Transverse strength or rigidity, 5. Expansive ratio, 6. Founding qualities, 7. Behaviour under files, cutting tools, &c., 8. Resistance to atmospheric influences, 9. Fitness to receive graduation, 10. Elasticity, 11. Fitness for being made into tubes, 12. Specific gravity—experiments were made to determine each of those conditions.

Tensile strength.—The result of trials by Mr. Anderson of Woolwich was—the average tenacity of this metal proved to be 22 tons 12 cwt. (50,624 lbs.) breaking weight per square inch. Elongations did not take place until 4,300 lbs. in the one case and 3,600 lbs. in the other had been applied, when a permanent elongation was noticed of ·009 of an inch in the first specimen and ·034 of an inch in the last

Resistance to compression.—The ultimate amount of compression applied was 59 tons 2 cwt. 1 qr. 4 lbs. (132,416 lbs.), under which the specimen became much distorted. "The specimen subjected to this enormous pressure, distorted though it is, does not exhibit the trace of a fissure. The cohesion of its particles is inviolate." Compression was not perceptible until 9 tons 2 cwt. per square inch (20,384 lbs.) was applied, when the specimen gave way to the extent of ·006 of an inch; and on the weight being removed an elasticity of ·001 was observed, which gives the first permanent compression as ·005 of an inch.

Malleability.—The quality of this metal for forging purposes would appear to be excellent. There were specimens in the International Exhibition of 1862 showing that the alloy could be drawn out under the hammer almost to a needle-point.

* The present price of aluminium in London is 5*s.* per ounce, whilst only in March 1856, just after M. Deville's experiments had been made, it cost 3*l.* per ounce.

Digitized by Google

Transverse strength.—These experiments were made by Messrs. Simms. The same weight applied to these bars altered the index of the instrument as under:—

Brass - - - - -	2·22 divisions
Gun Metal - - - - -	0·15 „
Aluminium Bronze - - - - -	0·05 „

Hence aluminium bronze is 3 times more rigid than gun-metal, and 44 times more rigid than brass.

Expansive ratio.—Aluminium bronze is affected by change of temperature a little less than gun-metal, and much less than brass.

Founding qualities.—The alloy produces admirable castings of any size.

Behaviour under files, cutting tools, &c.—"In this respect it leaves nothing to be desired. It does not clog the file; and in the lathe and planing-machine the tool removes long elastic shavings, leaving a fine, bright, smooth surface."

Resistance to atmospheric influences.—This alloy tarnishes much less readily than any metal usually employed—viz. gun-metal, brass, silver, cast-iron, or steel.

Fitness to receive graduation.—The lines are remarkably pure and equable, and very distinct under the microscope, notwithstanding the yellow colour of the metal.

Elasticity.—No wires tried for the suspension of Foucault's pendulum for illustrating the rotation of the earth were so durable—not even those of steel—under that severe ordeal as wires of aluminium bronze.

Fitness for being made into tubes.—It admits of every process necessary for this purpose.

Specific gravity.—The specific gravities of alloys of aluminium and copper, are:—

3	per cent of	aluminium	-	-	-	8·691
4	„	„	-	-	-	8·621
5	„	„	-	-	-	8·369
10	„	„	-	-	-	7·689

At the Elswick Works Captain Noble, R.A., confirmed previous experiments on the capability of aluminium bronze to resist longitudinal and transverse fracture; and in addition to this he ascertained that its position to withstand compression stood halfway between that of the finest steel and the best iron.

The bronze, containing 10 parts of aluminium and 90 of copper, affords an alloy endowed with the greatest strength, malleability, and ductility. The colour of the copper is affected by a very trifling addition of the other constituent, and the alloy gradually improves in these valuable qualities just mentioned, until the proportions given above are reached. After this—*i.e.* when more than ten per cent. of aluminium enters into the composition of the bronze—the alloy gradually becomes weaker and less malleable, and at length so brittle that it is easily pounded in a mortar.

ALUMINIUM, CHLORIDE OF (Al^2Cl^3—133·9). *Preparation.*—Chloride of aluminium cannot be prepared by treating alumina with hydrochloric acid, as in the case of most chlorides; for on evaporating the solution to dryness, hydrochloric acid is evolved and alumina alone remains.

The method at present used is, in principle, the same as that originally suggested by Œrsted, which has since found numerous other applications. It is impossible to convert alumina into the chloride by the direct action of chlorine alone; at any temperature the chlorine is as incapable of displacing the oxygen from the alumina as it would from lime. But if the attraction of the chlorine for the metal be supported by the affinity of carbon for the oxygen, then the compound is, as it were, torn asunder—carbonic acid or carbonic oxide resulting on the one hand, and the chloride of aluminium on the other.

On the large scale the chlorine is passed over a previously ignited mixture of clay and coal-tar, contained in retorts like those used in the manufacture of coal-gas, which are heated in a furnace; the chloride, which on account of its volatility is carried off, being condensed in a chamber lined with plates of earthenware, where it is deposited in a crystalline mass.

Properties.—It is a yellowish crystalline solid, readily decomposed by the moisture of the air into hydrochloric acid and alumina, volatile at a dull red heat. It is very soluble in water, but cannot be recovered by evaporating the solution.—H. M. W.

ALUMINIUM, FLUORIDE OF. (Al^2F^6) The existence of the fluoride of aluminium in nature, the form of the double fluoride of sodium and aluminium, namely, NaF, Al^2F^6, as kryolite, and the use of this mineral in the manufacture of aluminium, has been already alluded to. The fluoride of aluminium likewise exists in two other minerals, namely, the topaz $[3(Al^2O^3, SiO^3) + (Al^2O^3 + Al^2F^3)]$ and pycnite, $3(Al^2O^3, SiO^3) + Al^2F^3$.*

The pure fluoride can only be obtained artificially by dissolving pure aluminium

* Graham's Elements of Chemistry, i. 605.

Digitized by Google

in hydrofluoric acid. It has a great tendency to form double salts with the fluorides of potassium and sodium.—H. M. W.

ALUM, NATIVE. This term includes several compounds of sulphate of alumina with the sulphate of some other base, as magnesia, potash, soda, the protoxides of iron, manganese, &c. They occur generally as efflorescences, or in fibrous masses; when crystallised they assume octahedral forms, are soluble in water, and have an astringent taste.

ALUM, ROMAN (*Alumen Romanum. Alume di rocca*, It.), called sometimes *Roch* or *Rock Alum*. See ALUM.

ALUM SHALE. The chief natural source from which the alum of commerce is derived in this country. It occurs in a remarkable manner near Whitby, in Yorkshire, and at Hurlet and Campsie, near Glasgow. A full description of the alum shale, and of the processes by which the crystallisable alum is separated, will be found under ALUM.

ALUNITE, or ALUMSTONE (*Alun*, Fr.; *Alaunstein*, Germ.). This mineral is composed of alumina 37·13, sulphuric acid 38·53, potash 11·34, water 13·00. Silica is also frequently present as an impurity, sometimes to the extent of 60 per cent. It is a white, greyish, or reddish mineral, affording a white streak, and an uneven, flat, conchoidal fracture, which is splintery in the massive varieties. It is transparent or subtranslucent.

Alumstone is one of the sources of the alum of commerce, which is obtained from it in crystals after frequent roasting, and lixiviation in water.

Alumstone is found at Tolfa, near Civita Vecchia, in the Roman States (sometimes in crystals); at Elizabethpol, in Georgia; at Pic de Saucy, in France, and in the Grecian Archipelago. The compact varieties from Hungary are so hard as to be used for millstones.—*Dana*.

AMADOU. (*Amadou*, Fr.; *Zunderschwamm*, Gr.) The name of a spongy combustible substance, prepared from a species of agaric, the *boletus igniarius*, which grows on the trunks of cherry trees, ashes, beeches, &c.; it is sometimes known as *spunk*, and as touchwood, but commonly in this country it is called *German tinder*. It must be plucked in the months of August and September. This plant grows horizontally on the several trees on which it is indigenous: when it makes its first appearance it is a little round wart-like body, not larger than a pea; it gradually increases in size and hardness till it becomes of a darkish brown, and is as large as an apple. It afterwards takes a horizontal direction, forms a border, and becomes covered with numerous closely-packed tubes on its under-surface. The *Boletus fomentarius* is another indigenous fungus, found on the oak and birch. This is also used in preparing *Amadou*. It was formerly used in surgery, and has hence been called Surgeon's Agaric. Amadou is prepared by removing the outer bark with a knife, and separating carefully the spongy substance—of a yellow brown colour, which lies within it—from the ligneous matter below. This substance is cut into thin slices, and beaten with a mallet to soften it, till it can be easily pulled asunder between the fingers. In this state the *boletus* is a valuable substance for stopping oozing hæmorrhages, and some other surgical purposes. To convert it into tinder it must receive a finishing preparation, which consists in boiling it in a strong solution of nitre; drying it, beating it anew, and putting it a second time into the solution. Sometimes, indeed, to render it very inflammable, it is imbued with gunpowder, whence the distinction of black and brown amadou.

All the puff-balls of the *lycopodium* genus of plants, which have a fleshy or filamentous structure, yield a tinder by soaking in gunpowder water. The Hindoos employ a leguminous plant, which they call *solu*, for the same purpose. Its thick spongy stem, being reduced to charcoal, takes fire like amadou. See AGARIC.

AMALGAM. When mercury is alloyed with any metal, the compound is called an amalgam of that metal; as, for example, an amalgam of tin, bismuth, &c.

Some amalgams are solids and others fluids; the former are often crystalline, and the latter may be probably regarded as the solid amalgam dissolved in mercury.

Silver Amalgam may be formed by mixing finely-divided silver with mercury. The best process is to precipitate silver from its solution by copper, when we obtain it in a state of fine powder, and then to mix it with the mercury.

A native amalgam of mercury and silver occurs in fine crystals in the mines of the Palatinate of Moschellandsberg: it is said to be found where the veins of copper and silver intersect each other. Dana reports its existence in Hungary and Sweden, at Allemont, in Dauphiné; Almaden, in Spain, and in Chili; and he quotes the following analyses:—

	Silver.	Mercury.
Moschellandsberg	36·0	64·0 by Klaproft.
Ditto	25·0	73·3 „ Heyer.
Allemont	27·5	72·5 „ Cordier.

If six parts of a saturated solution of nitrate of silver with two parts of a saturated

Digitized by Google

solution of the protonitrate of mercury are mixed with an amalgam of silver one part and mercury seven, the solution is speedily filled with beautiful arborescent crystals —the *Arbor Dianæ*, the tree of Diana,—or the silver tree.

Gold Amalgam is made by heating together mercury with grains of gold, or gold-foil; when the amalgam of gold is heated, the mercury is volatilised and the gold left. This amalgam is employed in the process known as that of fire gilding, although, since electro-gilding has been introduced, it is not so frequently employed. A gold amalgam is obtained from the platinum region of Columbia; and it has been reported from California, especially from near Mariposa. Schneider gives its composition, mercury, 57·40; gold, 38·89; silver, 5·0.

Tin Amalgam.—By bringing tinfoil and mercury together, this amalgam is formed, and is used for silvering looking-glasses. (See SILVERING GLASS.) If melted tin and mercury are brought together in the proportion of three parts mercury and one part tin, the tin amalgam is obtained in cubic crystals.

Electric Machine Amalgam.—Melt equal parts of tin and zinc together, and add three parts of mercury; the mass must be shaken until it is cold, and rubbed down with some lard to give it the proper consistence.

Sodium Amalgam, used for separating gold from its ores. See GOLD, SILVER.

Copper Amalgam.—The French dentists have long made use of this for stopping teeth. It is sold in small rolls of about a drachm and a half in weight; it is covered with a greyish tarnish, has a hardness much greater than that of bone, and its cohesion and solidity are considerable. When heated nearly to the point of boiling water this amalgam swells up, drops of mercury exuding, which disappear again on the cooling of the substance. If a piece, thus heated, be rubbed up in a mortar, a plastic mouldable mass, like poor clay, is obtained, the consistence of which may, by continued kneading, be increased to that of fat clay. If the moulded mass be left for ten or twelve hours, it hardens, acquiring again its former properties, without altering its specific gravity. Hence the stopping, after it has hardened, remains tightly fixed in the hollow of the tooth. The softening and hardening may be repeated many times with the same sample. Pettenkofer ascribes these phenomena to a state of amorphism, with which the amalgam passes from the crystalline condition in the process of softening. All copper amalgams containing between 0·25 to 0·30 of copper exhibit the same behaviour. The above chemist recommends, as the best mode of preparing this amalgam, that a crystalline paste of sulphate of suboxide of mercury (prepared by dissolving mercury in hydrated sulphuric acid at a gentle heat) be saturated under water at a temperature of from 60° to 70°, with finely divided reguline copper (prepared by precipitation from sulphate of copper with iron). One portion of the copper precipitates the mercury, with formation of sulphate of copper; the other portion yields with mercury an amalgam: 100 parts of dissolved mercury require the copper precipitated, by iron, from 232·5 parts of sulphate of copper. As in dissolving the mercury the protoxide is easily formed instead of the suboxide, particularly if too high a temperature be maintained, it is advisable, in order to avoid an excess of mercury in the amalgam, to take 223 parts of sulphate of copper, and to add to the washed amalgam, which is kept stirred, a quantity of mercury in minute portions, corresponding to the amount of suboxide contained in the mercury salt, until the whole has become sufficiently plastic. This amalgam may be obtained by moistening finely-divided copper with a few drops of a solution of nitrate of suboxide of mercury, and then triturating the metal with mercury in a warmed mortar. The rubbing may be continued for some time, and may be carried on under hot water, mercury being added until the required consistence is attained.

A remarkable depression of temperature during the combination of amalgams has been observed by several chemists.

Dobereiner states that when 816 grains of amalgam of lead (404 mercury and 412 lead) were mixed, at a temperature of 68°, with 688 grains of the amalgam of bismuth (404 mercury and 284 bismuth) the temperature suddenly fell to 30°, and by the addition of 808 grains of mercury (also at 68°) it became as low as 17°; the total depression amounting to 51°.

In certain proportions of mixture of the constituents of fusible metal (tin, lead, and bismuth) with mercury, Dobereiner formed surprising depressions of temperature; the temperature, he records of one experiment, sank instantly from 65° to 14°.

AMALGAMATION. See GOLD and SILVER.

AMARINE. (C^{42} H^{18} N^2) An organic base produced from bitter-almond oil.

AMAZON STONE. A bluish-green variety of Felspar (Orthoclase). It is found at Lake Ilmen in Russia of a verdigris-green variety. That from Baikai in Siberia is composed of silvery spangles in a green base, of which small vases and other ornaments are made.

AMBAR, LIQUID. (*Ambre, Liquide*, Fr.) In former editions of this Dictionary, the

Digitized by Google

liquid-ambar, as it was called, was confounded with liquid storax or styrax. It is obtained from the *liquid-ambar styraciflua* of Linnæus, growing in Louisiana and Mexico, whereas the *storax* is procured chiefly—it is now entirely—from Trieste; and it is extracted from the *styrax officinalis*, which grows in various parts of Greece. Pereira, quoting Buchner's "Repertorium," informs us that the storax is known in the East as *buchuri-jag*. Liquid-ambar is rarely used in any art or manufacture. It is brownish ash-grey, of the consistence of turpentine, dries up readily, smells agreeably, like benzoin, has a bitterish, sharp, burning taste; is soluble in 4 parts of alcohol, and contains only 1·4 per cent. of benzoic acid.

AMBER. (*Succin*, Fr.; *Bernstein*, Germ.) The *Electron* of the Greeks, to whom this substance appears to have been well known. From its peculiar property of manifesting electrical phenomena, we have derived our word, *electricity*. It appears to have been known to the Romans under the names of *lyncurium*, and, because of its supposed vegetable origin, *succinum*. The ancients also gave the name *electrum* to a yellow metal containing gold and silver. See ELECTRUM.

Amber is a mineral solid, of a yellow colour of various shades, which burns quite away with flame, and consists of carbon, hydrogen, and oxygen, in nearly the same proportions, and in the same state of combination, as vegetable resin. The chemical composition, according to *Schrötter*, is:—

Carbon	78·82
Hydrogen	10·22
Oxygen	10·9

Its specific gravity varies, by Dr. Ure's trials, from 1·080 to 1·085. It becomes negatively and powerfully electrical by friction. When applied to a lighted candle it takes fire, swells considerably, and exhales a white smoke of a pungent odour; but does not run into drops. Copal, which resembles it in several respects, differs in being softer, and in melting into drops at the flame; and mellite, or honey-stone, which is a mineral of a similar colour, becomes white when laid on a red-hot coal.

The texture of amber is resino-vitreous, its fracture conchoidal, and lustre glassy. It is perfectly homogeneous; sufficiently hard to scratch gypsum, and to take a fine polish. It is, however, scratched by calcareous spar. When amber is distilled in a retort, crystalline needles of succinic acid sublime into the dome, and oil of amber drops from the beak into the receiver. Fossil resins, such as that of Highgate, found in the London clay formation, do not afford succinic acid by heat; nor does copal. Amber is occasionally found of a whitish and brownish colour. The Rev. F. W. Hope, F.R.S., in his paper on the "Succinic Insects," states them to be altogether extra-European. "Amber is occasionally met with in the gravel-pits near London, and I have seen specimens which were found in Hyde Park. At Aldborough after a raking tide, it is thrown on the beach in considerable quantities, along with masses of jet.—*Rev. F. W. Hope*, Trans. Ent. Soc.

The most interesting fact relative to this vegeto-mineral is its geological position, which is very characteristic and well determined. It is found almost uniformly in separate nodules, disseminated in the sand, clay, or fragments of lignite of the plastic clay formation, situated between the *calcaire grossier* (crag limestone) of the tertiary strata above, and the white chalk below. The size of these nodules varies from a nut to a man's head; but this magnitude is very rare in true amber. It does not occur either in continuous beds, like the chalk flints, or in veins; but it lies at one time in the earthy or friable strata which accompany or include the lignites; at another entangled in the lignites themselves. The pieces of amber found in the sands, and other formations evidently alluvial, those met with on the sea-coasts of certain countries, and especially Pomerania, come undoubtedly from the above geological formation; for the organic matters found still adhering to the amber leave no doubt as to its primitive place. Amber does not, therefore, belong to any postdiluvian or modern soil, since its native bed is covered by three or four series of strata, often of considerable thickness, and well characterised, proceeding upwards from the plastic clay which includes the amber: these are, the crag limestone, the bone gypsum, with its marls, the marly limestone, the upper marl sandstone, which covers it, and, lastly, the freshwater or lacustrine formation, often so thick, and composed of calcareous and siliceous rocks.

The amber bed is not, however, always covered with all these strata; and it is even rare to see a great mass of one of them above the ground which contains it: because, were it buried under such strata, it would be difficult to meet with such circumstances as would lay it spontaneously open to the day. The true yellow amber belongs therefore to the Plastic clay formation intermediate in England between the chalk and the London clay. The vegetable origin of amber is satisfactorily determined by its chemical composition,—its optical properties, as shown by Sir David Brewster,—and by the condition in which insects and the remains of insects

Digitized by Google

are found in this resin, along with fragments of leaves and stalks. Certain families of insects occur more abundantly than others. Thus the *hymenoptera*, or insects with four marked membranaceous wings, as the bee and wasp, are not abundant. The *diptera*, or insects with two wings, as gnats and flies, are more numerous. Then come the spider tribe, some *coleoptera* (insects with crustaceous shells or elytra, which shut together and form a longitudinal suture down the back), or beetles—principally those which live on trees, as the *elaterides*, or leapers, and the *chrysomelida*. The insects appear evidently to have struggled after being entangled in the then viscous fluid, and occasionally a leg or a wing is found at some distance from the body, which had been detached in the efforts of the insect to escape from the resin. Göppert has named the tree supposed to have yielded the amber, *Pinites succinifer*.

Germar and Schweiger state that the insects enveloped in amber are in general such as sit on the trunks of trees, or live in the fissures of their bark. These naturalists have not been able to refer them to any living species; but it has been observed that they resemble more the insects of hot climates than those of the temperate zones. D. T. Tessler sent to the Exhibition in 1851, a piece of amber containing the leg of a toad. Amber is found abundantly on the Prussian coast of the Baltic, occuring from Dantzic to Memel, especially between Pillau and Dorfe Gross-Hubnicken. It occurs also on the coast of Denmark and Sweden; in Gallicia, near Lemberg, and at Missan, in Poland; in Moravia, at Boskowitz; in the Uralian Mountains, Russia; near Christiania, Norway; in Switzerland, near Basle, and other places. Small quantities are occasionally found in the clay of the Paris and the London basins. On the Sicilian coast amber is sometimes found having a peculiar blue tinge.

Amber is collected on the coast of Prussia in several ways. It is found in the beds of streams; in the sand-banks of rivers; in pieces thrown up by the sea and rounded by the waves; it is sought for in the cliffs, and in some places mining operations for it are carried on.

The amber fishers, clothed in leather dresses, wade into the sea, and seek to discover the amber floating on its surface, which they secure with bag nets hung at the ends of long poles. They conclude that much amber has been detached from its bed, when they discover many pieces of lignite floating about. Mining is carried on by sinking through the sand and superficial strata to the beds containing the amber and lignite; many of these pits are sunk to the depth of 130 feet. The faces of the precipitous cliffs are explored in boats, and masses of loose earth or rock supposed to contain the object of search are detached with long poles having iron hooks at their ends.

The most extensive use of amber is for the construction of mouth-pieces to pipes; these form an essential constituent of the genuine meerschaum and the Turkish pipe. There is a current belief in Turkey that amber is incapable of transmitting infection, and as it is a great mark of politeness to offer the pipe to a stranger, this supposed negative property of amber accounts in some measure for the estimation in which it is held. Amber necklaces are not uncommon: the Russian peasant girls adorn themselves with double and treble rows of amber beads, but it not unfrequently happens that copal is substituted for the genuine article.

The Prussian government is said to draw an annual revenue of 17,000 dollars from amber. A good piece of a pound weight fetches 50 dollars. A mass weighing 13 pounds has been found, the value of which at Constantinople was said to be not less than 30,000 dollars.

When amber is to be worked into trinkets, it is first split on a leaden plate at a lathe, and then smoothed into shape on a Swedish whetstone. It is polished on the lathe with chalk and water, or vegetable oil, and finished by friction with flannel.

Amber, after having been filed, may be polished with Trent sand, or scraped Flanders brick, on flannel with water, or with rottenstone with oil on flannel, or the same material dry on the hand. Turned works are, however, generally polished first with glass-paper and then with rottenstone and oil. Necklaces and other ornaments in amber are frequently cut into facets by the gold cutters, those artisans who cut and polish facetted works.—*Holtzapffel.*

From the electrical character of amber, it frequently during the process of polishing becomes so excited as to crack and fly to pieces. The workmen therefore take several pieces, and work them each for a short time and in regular order. These men are said to be seized with nervous tremors in their wrists and arms from the electricity thus developed.

Pieces of amber may be neatly joined by smearing their edges with linseed oil and pressing them strongly together while they are held over a charcoal fire.

In 1863 we imported of Rough Amber 70 cwt., valued at 627*l.*; and manufactured amber to the value of 87*l.* This does not appear to comprehend the amber mouth-pieces to pipes.

AMBER, ACID OF. See SUCCINIC ACID.

AMBER, OIL OF. (*Oleum succini.*) This is obtained by distilling amber, for which purpose chippings of amber and inferior pieces are used. When it is distilled with charcoal, the first product is the *rectified oil of amber*. The oil of amber has a composition C^{20} H^{16}. When 1 part of rectified oil of amber is dissolved in 24 parts of alcohol of ·830, and 96 of caustic ammonia of ·916, *eau de luce* is formed. Eau de luce was a celebrated old perfume, but it is now rarely made.

If nitric acid is poured into *eau de luce* a viscid resinous mass is formed, which has the smell of musk, and is known as *artificial musk*. Formerly this preparation, dissolved in alcohol, was considered as a specific in whooping-cough, and it was frequently administered in spasmodic diseases.

AMBER VARNISH. A strong and durable varnish is made by dissolving amber in drying linseed oil. The amber is, however, previously heated in an iron pot, over a clear red fire, till it softens and assumes a semifluid form. The oil, which has been also made hot, is to be poured on the melted amber, and the mixture diligently stirred.

The following proportions are stated to be the best:—16 ounces of amber and 10 ounces of linseed oil. When these are, by the above method, thoroughly incorporated, and the liquid is somewhat cooled, a pound of oil of turpentine must be added.

Black coachmaker's varnish is prepared by melting 16 ounces of amber and adding thereto about half a pint of boiling-hot drying linseed oil, 3 ounces of asphaltum, and the same quantity of resin. After these have been thoroughly mixed over the fire, the vessel containing the varnish is removed, and, after cooling, a pint of warm oil of turpentine is added.

Amber is composed of a mixture of two resins, which are soluble in alcohol and ether, and in some of the recently-discovered hydrocarbon compounds. Varnishes are therefore prepared with them, and sold under the name of *amber spirit varnishes*; but these are frequently composed of either copal or mastic. They have been much used for varnishing collodion pictures.

AMBERGRIS. (*Ambregris*, Fr.; *Ambra*, Germ.) A morbid secretion from the liver and intestines of the spermaceti whale (*Physeter macrocephalus*). It is found usually swimming on the sea upon the coasts of Coromandel, Japan, the Moluccas, and Madagascar, and also on various parts of the east coast of Africa. Ambergris has not been found in any whales but such as have been dead or sick; its production has therefore been attributed to disease. As portions of the food of the whale are invariably found in any large pieces of ambergris, there is little doubt that it originates in the intestines of that animal.

The best ambergris is ash-coloured, with yellow or blackish veins or spots, scarcely any taste, and very little smell unless heated or much handled, when it yields an agreeable odour. Exposed in a silver spoon it melts without bubble or scum, and on the heated point of a knife it vaporises completely away.

The Chinese try the genuineness of ambergris by scraping it fine upon boiling tea; it should dissolve and diffuse itself generally. Black or white is bad; the smooth and uniform is generally factitious. It has often a black streak, or is marbled yellow and black; has a fatty taste, is lighter than water, melts at 60° C. (140° F.), dissolves readily in absolute alcohol, in ether, and in both fat and volatile oils. It contains $85\frac{2}{3}$ of the fragrant substance called *ambreine*.

The chemical composition of ambergris is represented by the following formula, C^{30} H^{52} O. True ambergris is very rarely met with, by far the largest proportion of that which is sold as ambergris being a preparation scented with *civet* or *musk*. The alcoholic tincture of ambergris is highly fluorescent in sunlight, exhibiting a characteristic yellow green rim on the surface of the solution. This is a test by which genuine ambergris may be distinguished from such as is spurious.

Capt. Alex. Hamilton, in his "Thirty Years' Experience," says, "Sometimes, in the south-west monsoons, they find ambergrease floating on the sea. I saw a piece in Adda Rajah's possession as big as a bushel; and he valued it at 10,000 rupees, or 1.250*l.* sterling." This was at the Laccadive Islands, 170 miles from the Malabar Coast.—*New Account of the East Indies*, 1688 *to* 1730.

In France the duty upon ambergris is 62 francs per kilogramme when imported in French vessels, and 67 francs when imported in foreign vessels.

Ambergris is at this time (1865) worth 20*s.* an ounce in England. Mr. Temple, of British Honduras, speaks of an odorous substance thrown off by the alligator, which appears to resemble ambergris.

AMBREINE. The fragrant substance of ambergris, which may be obtained by digesting ambergris in hot alcohol, from which, on cooling, it is deposited in a crystalline form. It is composed of C 88·37, H 3·32, O 3·31.

AMETHYST (*Améthyste occidentale*, Fr.; *Eisenkeisel*, Germ.) One of the vitreous varieties of quartz, composed of pure silica in the insoluble state—that is, it

Digitized by Google

will not dissolve in a potash solution. It belongs to the rhombohedral system, and is found either in groups of crystals or lining the interior of geodes and pebbles. It is infusible before the blowpipe, and is not affected by acids. It is of a clear purple or bluish-violet tint; but the colour is frequently irregularly diffused, and gradually fades into white. The colour is supposed to be due to the presence of a small percentage of manganese, but Heintz attributes it to a compound of iron and soda. The amethyst, from the beauty of its colour, has always been esteemed and used in jewellery. It was one of the stones called by the ancients ἀμέθυστος, a name which they conferred on it from its supposed power of preserving the wearer from intoxication. The most beautiful specimens are procured from India, Ceylon, and Persia, where they occur in geodes and pebbles: it is also found at Oberstein, in Saxony; in the Palatinate; in Transylvania; near Cork, and in the Island of May, in Ireland.—H. W. B.

AMETHYST, ORIENTAL. (*Améthyste orientale*, Fr.; *Demanthspath*, Germ.) This term is applied to those varieties of corundum which are of a violet colour. See CORUNDUM.—H. W. B.

AMIANTHUS is the name given to the whiter and more delicate varieties of asbestos, which possess a satin-like lustre, in consequence of the greater separation of the fibres of which they are composed. A variety of amianthus (the amianthoide of Haüy) is found at Oisans, in France, the fibres of which are in some degree elastic. The word amianthus (from ἀμίαντος, undefiled) is expressive of the easy manner by which, when soiled, it may be cleansed and restored to its original purity, by being heated to redness in a fire. See ASBESTOS.—H. W. B.

AMIDE. This term and *amidogen* are applied to a class of substances which contain ammonia deprived of an atom of hydrogen.

AMIDINE. A name given to the soluble portion of starch.

AMINES. Chemical substances resembling *Amides*, but containing basic radicals. See Watt's "Dictionary of Chemistry."

AMIDON. The name for starch on the Continent.

AMMONIA. NH^3, *eqv.* 17. (*Ammoniaque*, Fr.; *Ammoniak*, Germ.) The name given to the alkaline gas which is the *volatile alkali* of the early chemists. The real origin of this word is not known. Some suppose it to be from *Ammon*, a title of Jupiter, near whose temple in Upper Egypt it was generated. Others suppose it to be from *Ammonia*, a Cyrenaic territory; whilst others again have deduced it from ἄμμος, sand, as it was found in sandy ground.

It is propable that Pliny was acquainted with the pungent smell of ammonia. Dr. Black, in 1756, first isolated it, proving the distinction between it and its carbonate, with which it had been confounded up to that time; and it was soon afterwards more fully investigated by Priestley.

Ammonia being a product, not only of the destructive distillation of organic bodies containing nitrogen, but also of their decay, it exists in the atmosphere, in a large amount, if considered in the aggregate, although, by examining any particular specimen of air, the quantity appears small. Nevertheless, this small quantity of ammonia would seem to be exceedingly important in developing the nitrogenised constituents of plants. Liebig believes that the nitrogen of plants is exclusively derived from the ammonia present in the air; but the opinions of chemists are divided on this point. Boussingault* supports Liebig's view, but it is opposed by Mulder and Ville.

From the air, ammonia and its salts are carried down by the rain. This fact has been placed beyond all doubt by Liebig; and even the variations in the quantity have been determined by Boussingault, and more recently by Mr. Way. By the rain water it is carried into rivers, and ultimately into the sea, in which choride of ammonium has been detected by Dr. Marcet. It has likewise been detected in mineral springs, especially brine springs, and even in common salt.—*Vogel.*

Ammonia is present in the exhalations from volcanoes. During the eruption of Vesuvius in 1794, the quantity of sal ammoniac discharged by the mountain was so great, that the peasants collected it by hundredweights (*Bischof*); and in the last eruption of Hecla, in Sept., 1845, a similar phenomenon was observed; and, according to Ferrara, it is sometimes found in such quantity at Etna, that a very profitable trade has been carried on in it. Dr. Daubeny thinks that the volcanic ammonia is produced by the action of water upon mineral nitrides (perhaps the nitrides of silicon), similar in properties to the nitrides of Titanium and Boron, which have been recently more carefully examined M. St. Claire Deville. Ammoniacal salts have likewise been found as a sublimate arising from the combustion of coal strata.

The great supply of ammonia and its salts is derived from the destructive distillation of organic bodies, animal and vegetable, containing nitrogen; but its salts exist in plants, and to a much larger extent in the liquid and solid excrements of animals. As a urate, it forms the chief constituent of the excrement of the boa, as well as that of many birds, hence the large quantity of ammoniacal salts in guano. See GUANO.

Formation of Ammonia.—No process has yet been devised for inducing the direct combination of nitrogen and hydrogen to produce ammonia; but under the disposing influence of the production of other compounds, in the presence of these elements, as well as when these gases are presented to each other in the nascent state, their union is effected.

Thus, when electric sparks are passed through a mixture of nitrogen and oxygen in the presence of hydrogen and aqueous vapour, nitrate of ammonia is generated. If, while zinc is being dissolved in sulphuric acid, nitric acid be added, much ammonia is formed (*Nesbit*); so again, if hydrogen and binoxide of nitrogen be passed over spongy platinum, torrents of ammonia are produced, the hydrogen converting the oxygen of the binoxide into water, when the nitrogen, at the moment of its liberation, combines with the hydrogen to form ammonia.

It has even been proposed to carry out this last method on a manufacturing scale.

Messrs. Crane and Jullien, in their patent of January 18, 1848, describe a method of manufacturing ammonia in the state of carbonate, hydrocyanate, or free ammonia, by passing any of the oxygen compounds of nitrogen, together with any compound of hydrogen and carbon, or any mixture of hydrogen with a compound of carbon or even free hydrogen, through a tube or pipe containing any *catalytic* or contact substance, as follows:—Oxides of nitrogen (such for instance as the gases liberated in the manufacture of oxalic acid), however procured, are to be mixed in such proportion with any compound of carbon and hydrogen, or such mixture of hydrogen and carbonic oxide or acid as results from the contact of the vapour of water with ignited carbonaceous matters, and the hydrogen compound or mixture containing hydrogen may be in slight excess, so as to ensure the conversion of the whole of the nitrogen contained in the oxide so employed into either ammonia or hydrocyanic acid, which may be known by the absence of the characteristic red fumes on allowing some of the gaseous matter to come in contact with atmospheric air. The catalytic substance which Messrs. Crane and Jullien prefer is platinum, which may be in the state of sponge, or it may be asbestos coated with platinum. This catalytic substance is to be placed in a tube, and heated to about 600° F., so as to increase the temperature of the product, and at the same time prevent the deposition of carbonate of ammonia, which passes onwards into a vessel of the description well known and employed for the purpose of condensing carbonate of ammonia. The condenser for this purpose must be furnished with a safety pipe, to allow of the escape of uncondensed matter, and made to dip into a solution of any substance capable of combining with hydrocyanic acid or ammonia where they would be condensed. A solution of salt of iron is preferable for this purpose.*

Chemical Characters.—The gaseous ammonia liberated from its salts by lime (in a manner to be afterwards described) is a colourless gas of a peculiar pungent odour. It is composed, by weight, of 1 equivalent of nitrogen and 3 of hydrogen; or, by volume, of 2 measures of nitrogen and 6 of hydrogen, condensed to four; and may be resolved into these constituent gases by passing over spongy platinum heated to redness. By a pressure of 6·5 atmospheres at 50° F., it is condensed into a colourless liquid. It is combustible, but less so than hydrogen on account of the incombustible nitrogen which it contains; but its inflammability may be readily seen by passing it into an argand gas flame reduced to a minimum.

Ammonia is very soluble in water, cold water absorbing no less than 500 times its volume of this gas; and the solution has a less density and a lower boiling point than pure water. The following Table of the density of solutions of ammonia in water, of different strengths, is by Dr. Ure:—

Ammonia in 100.	Water in 100.	Specific Gravity by Experiment.	Ammonia in 100.	Water in 100.	Specific Gravity by Experiment.
26·500	73·500	0 9000	13·250	86·750	0·9455

Upon this variation in density of solutions of ammonia in proportion to their strength, Mr. J. J. Griffin has constructed a useful instrument called an *Ammonia-meter*. It is founded upon the following facts:—That mixtures of liquid ammonia with water possess a specific gravity which is the mean of the specific gravities of their components; that in all solutions of ammonia, a quantity of anhydrous ammonia, weighing 212½ grains, which he calls a *test-atom*, displaces 300 grains of water, and reduces the specific gravity of the solution to the extent of ·00125; and, finally, that the strongest solution of ammonia which it is possible to prepare at the temperature of 62° F. contains in an imperial gallon of solution 100 test-atoms of ammonia.

We extract the following paragraph from Mr. Griffin's paper in the Transactions of the Chemical Society, explanatory of the accompanying Table.

"The first column shows the *specific gravity* of the solutions; the second column the *weight* of an imperial gallon in pounds and ounces; the third column the *per-centage* of ammonia by weight; the fourth column the *degree* of the solution, as indicated by the instrument, corresponding with the number of *test-atoms* of ammonia present in a gallon of the liquor; the fifth column shows the number of *grains* of ammonia contained in a gallon; and the sixth column the *atomic volume* of the solution, or that *measure* of it which contains one test-atom of ammonia. For instance, one gallon of liquid ammonia, specific gravity 880, weighs 8 lbs. 128 oz. avoirdupois; its per-centage of ammonia, by weight, is 33·117; it contains 96 test-atoms of ammonia in one gallon, and 20400·0 grains of ammonia in one gallon; and, lastly, 104·16 septems containing one test-atom of ammonia. Although no hydrometer, however accurately constructed, is at all equal to the Centigrade mode of chemical testing, yet the Ammonia-meter, and the Table accompanying it, will be found very useful to the manufacturer, enabling him not only to determine the actual strength of any given liquor; but the precise amount of dilution necessary to convert it into a liquor of any other desired strength, whilst the direct quotation of the number of grains of real ammonia contained in a gallon of solution of any specific gravity will enable him to judge at a glance of the money-value of any given sample of ammonia.

Table of Liquid Ammonia (Griffin).

One Test-Atom of Anhydrous Ammonia = NH^3 weighs 212·5 grains. Specific Gravity of Water = 1·00000. One Gallon of Water weighs 10 lbs. and contains 10,000 Septems. Temperature 62° F.

Ammoniacal gas combines directly with hydrated acids, forming a series of salts, the constitution of which is peculiar, and must be here briefly discussed, that the formula hereafter employed in describing them may be understood.

These compounds may be viewed as direct combinations of the ammonia with the hydrated acids; thus, the compound with

Hydrochloric acid	as the	- Hydrochlorate (NH^3, HCl).
Hydrosulphuric acid	„	- Hydrosulphate (NH^3, HS).
Sulphuric acid	„	- Hydrated sulphate (NH^3; HO, SO^3).
Nitric acid	„	- Hydrated nitrate (NH^3; HO. NO^5).
Carbonic acid	„	- Hydrated carbonate (NH^3; HO, CO^2).

But the close analogy of these compounds, in all their properties, to the corresponding salts of potash and soda has led chemists to the assumption of the existence of a group of elements possessing the characters of a metal, of a basyl or hypothetical metallic radical, called ammonium (NH^4), in these salts; which theory of their constitution brings out the resemblance to the potash and soda salts more clearly, thus:—

The chloride		And the chloride	
of potassium contains	- KCl.	of ammonium contains	- NH^4Cl.
— sulphide „	- KS.	— sulphide „	- NH^4S.
— sulphate of potassa „	- KO, SO^3	— sulphate of ammonia	- NH^4O, SO^3
— nitrate „ „	- KO, NO^5	— nitrate „	- NH^4O,NO^5
— carbonate „ „	- KO, CO^2	— carbonate „	- NH^4O, CO^2

Although it may be objected to this view that the metal ammonium is not known, yet a curious metallic compound of this metal with mercury has been obtained; and, after all, it is by no means necessary that the metal should be isolated, for already the existence of numerous basic radicals has been assumed in organic chemistry which have never been isolated.

It is true, also, that the oxide of ammonium is unknown, but substitution-products of it have been produced, which are solid bodies, soluble in water, exhibiting all the characters of potash solution, being as powerfully caustic and alkaline. In fact, ammonia is in reality but the type of a vast number of compounds. It is capable of having its hydrogen replaced by metals (as copper, mercury, calcium, &c.), as well as by metallic or basic compound radicals, producing the endless number of artificial organic bases, which are primary, secondary, or tertiary nitrides, according as one, two, or three equivalents of the ammonia is replaced. When the substitution of the hydrogen in ammonia is effected by acid radicals, the compounds are called amides.

Preparation of Ammonia. — Ammonia is obtained by the decomposition of one of

Digitized by Google

the salts of ammonia, either the chloride of ammonium, NH^4Cl (sal ammoniac), or the sulphate, by a metallic oxide, *e.g.* lime.

$$NH^4Cl + CaO, HO = CaCl + NH^3 + 2HO.$$

On the small scale in the laboratory the powdered ammoniacal salt is mixed with slaked lime, in a Florence flask or a small iron retort, and gently heated; the ammoniacal gas being dried by passing it through a bottle containing lime. Chloride of calcium must not be employed in the desiccation of ammonia, since the ammonia is absorbed by this salt, producing a curious compound, the chloride of caliammonium, $N\left\{\begin{matrix}H^2\\Ca\end{matrix}\right\}Cl$, being, in fact, one of those substitution-compounds before alluded to.

The gaseous ammonia must be collected over mercury, on account of its solubility in water.

This operation is carried out on the large scale for the purpose of making the aqueous solution of ammonia (*liquor ammonia*, or *spirits of hartshorn*).

Solution of Ammonia.

Preparation.— In preparing the aqueous solution, the gas is passed into water contained in Woolfe's bottles, which on the small scale are of glass, whilst on the large scale they are made of earthenware.

A sufficiently capacious retort of iron or lead should be employed, which is provided with a movable neck; and it is desirable to pass the gas through a worm, to cool it, before it enters the first Woolfe's bottle. Each of the series of Woolfe's bottles should be furnished with a safety-funnel in the third neck, to avoid accidents by absorption. The whole of the condensing arrangements should be kept cool by ice or cold water.

Properties.— In the London and in the Edinburgh "Pharmacopœia" two solutions of ammonia are directed to be prepared, the stronger having the specific gravity 0·882, and containing about 30 per cent. of ammonia; the weaker of specific gravity 0·960, containing, therefore, about 10 per cent. of the gas.

Sometimes the commercial solution of ammonia is made by treating impure ammoniacal salts with lime, and it then contains empyreumatic oils; in fact, the various volatile products of the distillation of coal which are soluble in or miscible with water.

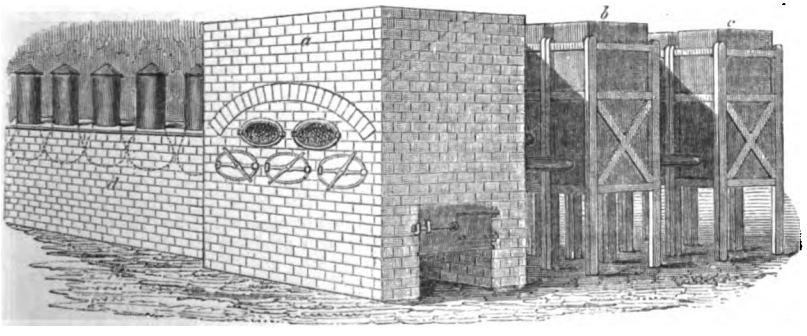
Pyrrol may be detected in ammonia by the purple colour which it strikes with an excess of nitric or sulphuric acid. If the residue of its distillation be mixed with potash, Picoline is detected by its peculiar odour. Naphthaline is discovered not only by its odour, but may also be separated by sublimation or heating, after converting the ammonia in the solution into a salt by sulphuric or hydrochloric acid.— *Dr. Maclagan.*

We *imported* into England of sulphate and liquor of ammonia as follows:—

Ammonia, sulphate of	- -	1856 - -	lbs. 23,904
,, ,,	- -	1855 - -	343,609
Ammonia, liquor	- -	1855 - -	22,400

Since, for the purpose of purification on the large scale, ammonia is invariably converted into chloride or sulphate, the details of the manufacture of the ammoniacal salts will be given under those heads. For the determination of ammonia, see NITROGEN.—H. M. W.

AMMONIA, CARBONATE OF. (*The sesquicarbonate* of commerce, $2NH^3$, $3CO^2$, $2HO = NH^4O, CO^2$; $HO, CO^2 + NH^2CO^2$, *eqv.* 118.) This salt was probably



Digitized by Google

known to Raymond Lully and Basil Valentine, as the chief constituent of putrid urine. The real distinction between ammonia and its carbonate was pointed out by Dr. Black.

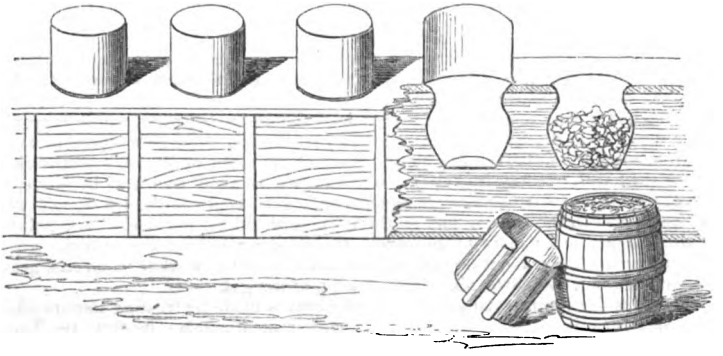
Carbonate of ammonia is formed during the putrefaction of animal substances, and by their destructive distillation. Its presence in rain water has been before alluded to

The carbonate of ammonia of commerce is obtained by submitting to sublimation a mixture either of sal ammoniac or sulphate of ammonia with chalk.

This is generally carried out in cast-iron retorts, similar in size and shape to those used in the manufacture of coal gas. The retorts are charged through a door at one end, and at the other they communicate with large square leaden chambers, supported by a wooden frame, in which the sublimed salt is condensed. *Fig.* 36, p. 135.

The product of this first process is impure, being especially discoloured by the presence of carbonaceous matter, and has to be submitted to resublimation. This is carried out in iron pots surmounted by movable leaden caps. These pots are either set

37



in brickwork, and heated by the flue of the retort furnace, or are placed in a water-bath, as shown in *fig.* 37. In fact, a temperature not exceeding 150° F. is found sufficient.

The charge of a retort consists usually of about 65 lbs. of sulphate of ammonia (or an equivalent quantity of the chloride) to 100 lbs. of chalk, which yield about 40 lbs of crude carbonate of ammonia.

Modifications of the Process.— Mr. Laming has suggested to bring ammonia and carbonic acid gases into mutual contact in a leaden chamber having at the lower part a layer of water, and then to crystallise the salt by evaporating this aqueous solution.

He also proposes to prepare carbonate of ammonia from the sulphide of ammonium of gas liquors, by passing carbonic acid gas into the liquor, which carbonic gas is generated by heating a mixture of oxide of copper and charcoal, in the proportion of twelve parts of the former to one of the latter.

Mr. Hill has described his mode of obtaining sesquicarbonate of ammonia from guano. To effect this, the guano is first mixed with charcoal or powdered coke: the mixture is then heated, and the sesquicarbonate of ammonia obtained by sublimation. The process does not appear to be much employed.

Manufacture of Ammonia from Peat and Shale.—Mr. Hills, in his patent of August 11th, 1846, specified the following method of obtaining ammonia from peat. The peat is placed in an upright furnace and ignited; the air passes through the bars as usual, and the ammonia is collected by passing the products of combustion through a suitable arrangement of apparatus to effect its condensation. This plan of obtaining ammonia from peat appears to be precisely similar to that patented by Mr. Rees Reece (January 23rd, 1849), and made to form an important feature in the operations of the British and Irish Peat Company. The first part of Mr. Reece's patent is for an invention for causing peat to be burned in a furnace by the aid of a blast, so as to obtain inflammable gases and tarry and other products from peat. For this purpose, a blast furnace with suitable condensing apparatus is used. The gases, on their exit from the condensing apparatus, may be collected for use as fuel or otherwise; and the tarry and other products pass into a suitable receiver. The tarry products may be employed to obtain paraffine and oils for lubricating machinery, &c.; and the other products may be made available for evolving ammonia, wood spirit, and other matters by any of the existing processes. Dr. Hodges, of Belfast, states that in his experiments he obtained nearly 22½lbs. of sulphate of ammonia from a ton of peat. Sir Robert Kane, who

Digitized by Google

was employed by Government to institute a series of experimental researches on the products obtainable from peat, states that he obtained sulphate of ammonia at the rate of $24\frac{4}{10}$ lbs. per ton of peat. Messrs. Drew and Stocken patented, in 1846, the obtaining ammonia from peat by distillation in close vessels, as practised in the carbonisation of wood. It will thus be seen that the peat is a source of ammonia, but that this source is a profitable or economical one, in a commercial point of view, is a problem in process of solution.

Ammonia from Schist.—Another source of ammonia is bituminous schist, which, when submitted to destructive distillation, gives off an ammoniacal liquor which may be employed in the manufacture of ammoniacal salts by any of the usual processes. The obtaining of ammonia from schist forms part of a patent granted to Count de Hompesch, September 4, 1841.

Chemical Composition and Constitution.—The true neutral carbonate of ammonia (NH^4O, CO^2) does not appear to exist. The sesquicarbonate of ammonia of the shops was found by Rose to have the composition assigned to it by Mr. Philips, *i. e.* it contains $2NH^3, 3CO^2, 2HO$; and it may therefore be viewed as a compound of the true bicarbonate (*i. e.* the double carbonate of ammonia and water), NH^4O, CO^2; HO, CO^2, with a peculiar compound of anhydrous carbonic acid with ammonia itself (NH^3, CO^4).

The equation representing its method of preparation will then be,

$$3NH^4O,SO^3 + 3CaO,CO^2 = (NH^4O,CO^2; HO,CO^2 + NH^3,CO^4) + NH^4O + 3CaO,SO^3$$
or $$3NH^4Cl + 3CaO,CO^2 = (NH^4O,CO^2,HO,CO^2 + NH^3,CO^2 + NH^4O) + 3CaCl,$$

for it is invariably found that a certain quantity of water and ammonia are liberated during the distillation, and hence the anomalous character of the compound. In fact, in operating upon 3 equivalents of the sulphate or chloride of the 3 equivalents of the true carbonate of ammonia (NH^4O, CO^2) which may be supposed to be generated, two are decomposed, one losing an equivalent of ammonia, the other an equivalent of water; of course, the ammonia thus liberated is not lost; it is passed into water to be saturated with acid, and thus again converted into sulphate or chloride.

Properties.—Sesquicarbonate of ammonia (as it is commonly called) is met with in commerce in the form of fibrous white translucent cakes, about two inches thick.

When exposed to the air the constituents of the less stable compound NH^3, CO^2 are volatilised, and a white opaque mass of the true bicarbonate remains. Hence the odour of ammonia always emitted by the commercial carbonate. Mr. Scanlan has also shown that by treatment with a small quantity of water, the carbonate is dissolved, leaving the bicarbonate. It is soluble in four times its weight of cold water, but boiling water decomposes it.

Impurities.—The commercial salt is sometimes contaminated with empyreumatic oil, which is recognised by its yielding a brownish coloured solution on treatment with water.

It may contain sulphate and chloride of ammonium. For the recognition of the presence of these acids, see SULPHURIC and HYDROCHLORIC Acids.

Sulphide and hyposulphite of ammonia are sometimes present, and likewise lead, from the chambers into which the salt has been sublimed.

Other Carbonates of Ammonia.—Besides the neutral or monocarbonate of ammonia before alluded to, the true bicarbonate ($NH^4O, CO^2; HO, CO^2$) and the sesquicarbonate of the shops, Rose has described about a dozen other definite compounds; but, for their description, we must refer to Watts' "Dictionary of Chemistry."

AMMONIACUM, GUM. Gum-resin. (*Gomme Ammoniaque*, Fr.; *Ammoniak*, Germ.) This is the inspissated juice of an umbelliferous plant (the *dorema armeniacum*), the gum-bearing heracleum, which grows in Persia, the East Indies, and Africa. In the French colony of Algiers this plant grows naturally, and it appears likely to become an object of cultivation. It comes to us either in small white tears clustered together, or in brownish lumps, containing many impurities. It possesses a peculiar smell, somewhat like that of assafœtida, and a bitterish taste. It is employed in medicine. Its only use in the arts is for forming a cement to join broken pieces of china and glass, which may be prepared as follows: Take isinglass 1 ounce, distilled water 6 ounces, boil together down to 3 ounces, and add $1\frac{1}{2}$ ounce of strong spirit of wine;—boil this mixture for a minute or two; strain it; add, while hot, first, half an ounce of milky emulsion of gum ammoniac, and then 5 drachms of an alcoholic solution of resin mastic.

AMMONIA, NITRATE OF.—This salt is not made on an extensive scale; but as it has a certain consumption for making the protoxide of nitrogen (laughing gas), a few remarks respecting it may not be out of place here.

It is obtained by saturating solution of ammonia, or the carbonate, with nitric acid, and then evaporating the solution till crystallisation takes place.

Digitized by Google

This salt crystallises in six-sided prisms, being isomorphous with nitrate of potash. Its composition is NH^4O, NO^5. It is incapable of existing without the presence of an equivalent of water, in addition to NH^3 and NO^5. If heat be applied, the salt is entirely decomposed into protoxide of nitrogen and water; thus—

$$NH^4O, NO^5 = 2NO + 4HO.$$

Besides its use in the laboratory for making protoxide of nitrogen, it is a constituent of frigorific mixtures, on account of the cold which it produces on dissolving in water.

Lastly, it is very convenient for promoting the deflagration of organic bodies, both its constituents being volatile on heating.

AMMONIA, SULPHATE OF. (NH^4O, SO^3) This salt is found native in fissures near volcanoes, under the name of *mossagnine*, associated with sal ammoniac. It also forms in ignited coal-beds—as at Bradley, in Staffordshire—with chloride of ammonium.

This salt is prepared by saturating the solution of ammonia, obtained by any of the processes before described (either from animal refuse, from coal, in the manufacture of coal-gas, from guano, or from any other source), with sulphuric acid, and then evaporating the solution till the salt crystallises out.

Frequently, instead of adding the acid to the ammoniacal liquor, the crude ammoniacal liquor is distilled in a boiler, either alone or with lime, and the evolved ammonia is passed into the sulphuric acid, contained in a large tun or in a series of Woolfe's bottles; or a modification of Coffey's still may be used with advantage, as in the case of the saturation of hydrochloric acid by ammonia.

If Coffey's still be employed, a considerable concentration of the liquor is effected during the process of saturation, which is subsequently completed generally in iron pans; but great care has to be taken not to carry the evaporation too far, to avoid decomposition of the sulphate by the organic matter invariably present, which reduces it to the state of sulphite, hyposulphite, and even to sulphide, of ammonium.

The salt obtained by this first crystallisation is much purer than the chloride produced under similar circumstances, and one or two re-crystallisations effect its purification sufficiently for all commercial purposes.

It is on account of the greater facility of purification which the sulphate affords by crystallisation than the chloride of ammonium, that the former is often produced as a preliminary stage in the manufacture of the latter compound, the purified sulphate being then converted into sal ammoniac by sublimation with common salt. The acid mother-liquor left in the first crystallisation is returned to be again treated, together with some additional acid, with a fresh quantity of ammonia.

Preparation. Modifications in details and patents. — Since it is in the production of the sulphate of ammonia that the modification of Coffey's still, called the *ammonia still*, is generally employed, it may be well to introduced here a detailed account of its arrangement.

This apparatus is an upright vessel, divided by horizontal diaphragms or partitions into a number of chambers. It is proposed to construct the vessel of wood, lined with lead, and the diaphragms of sheet iron. Each diaphragm is perforated with many small holes, so regulated, both with regard to number and size, as to afford, under some pressure, passage for the elastic vapours which ascend, during the use of the apparatus, to make their exit by a pipe opening from the upper chamber. Fitted to each diaphragm are several small valves, so weighted as to rise whenever elastic vapours accumulate under them in such quantity as to exert more than a certain amount of pressure on the diaphragm. A pipe also is attached to each diaphragm, passing from about an inch above its upper surface to near the bottom of a cup or small reservoir, fixed to the upper surface of the diaphragms next underneath. This pipe is sufficiently large to transmit freely downwards the whole of the liquid which enters for distillation at the upper part of the upright vessel and the cup or reservoir; into which the pipe dips forms, when full of liquid, a trap by which the upward passage of elastic vapours by the pipe is prevented. The vessel may rest on a close cistern, contrived to receive the descending liquid as it leaves the lowest chamber, and from this cistern it may be run off, by a valve or cock, whenever expedient. The cistern, or in its absence the lowest chamber, contains the orifice of a pipe which supplies the steam for working the apparatus. The exact number of chambers into which the upright vessel is divided is not of essential importance; but the quantity of liquid and the surface of each diaphragm being given, the distillation, within certain limits, will be more complete the greater the number of chambers used in the process. The liquid undergoing distillation in this apparatus necessarily covers the upper surface of each diaphragm to the depth of about an inch, being prevented from passing downward through the small perforations by the upward pressure of the rising steam and other elastic vapours; and, on the other hand, the steam being

Digitized by Google

prevented, by the traps, from passing upwards by the pipes, is forced to ascend by the perforations in the diaphragms; so that the liquid lying on them becomes heated, and in consequence gives off its volatile matters. When the ammoniacal liquid accumulates on one of the diaphragms to the depth of an inch, it flows over one of the short pipes into the trap below, and overflows into the next diaphragm, and so on. See DISTILLATION.

The management of the apparatus varies in some measure with the form in which it is desirable to obtain the ammonia. When the ammonia is required to leave the upper chamber in the form of gas, either pure or impure, it is necessary that the steam which ascends and the current of ammoniacal liquid which descends, should be in such relative proportions that the latter remain at or near the atmospheric temperature during its passage through some of the upper chambers, becoming progressively hotter as it descends, until it reaches the boiling temperature; in which state it passes through the lower chambers, either to make its escape, or to enter a cistern provided to receive it, and in which it may for some time be maintained at a boiling heat. On the contrary, if the ammonia, either pure or impure, be required to leave the upper chamber in combination with the vapour of water, the supply of steam entering below must bear such proportion to that of the ammoniacal liquid supplied above, that the latter may be at a boiling temperature in the upper part of the apparatus.*

The use of this apparatus has been patented in the name of Mr. W. E. Newton, Nov. 9, 1841.

Mr. Hill's process, patented Oct. 19, 1848, for concentrating ammoniacal solutions by causing them to descend through a tower of coke through which steam is ascending, is, in fact, nothing more than a rough mode of carrying out the same principle which is more effectually and elegantly performed by the modification of Coffey's still above described. The concentrated ammonia liquor is then treated with acid and evaporated in the usual way.

Mr. Wilson has patented, Dec. 7, 1850, another method of saturating the ammonia with the acid by passing the crude ammonia vapour, obtained by heating the ammoniacal liquor of the gas-works, in at the bottom of a high tower filled with coke, whilst the sulphuric acid descends in a continuous current from the top; in this manner the acid and ammonia are exposed to each other over a greatly extended surface.

Dr. Richardson (patent, Jan. 26, 1850) mixes the crude ammonia liquors with sulphate of magnesia, then evaporates the solution, and submits the double sulphate of magnesia and ammonia, which separates, to sublimation; but it would not appear that any great advantage is derived from proceeding in this way, either pecuniary or otherwise.

Mr. Laming passes sulphurous acid through the gas liquor, and finally oxidises the sulphite thus obtained to the state of sulphate, by exposure to the air. (Patent, Aug. 12, 1852.)

Michiel's mode of obtaing sulphate of ammonia, patented April 30, 1850, is as follows:—The ammoniacal liquors of the gas-works are combined with sulphate and oxide of lead, which is obtained and prepared in the following way:—Sulphuret of lead in its natural state is taken and reduced to small fragments by any convenient crushing apparatus. It is then submitted to a roasting process, in a suitably arranged reverberatory furnace of the following construction:—The furnace is formed of two shelves, or rather the bottom of the furnace and one shelf, and there is a communication from the lower to the upper. The galena or sulphuret of lead, previously ground, is then spread over the surface of the upper shelf, to a thickness of about 2 or 2¼ inches, and there it is submitted to the heat of the furnace. It remains thus for about two hours, at which time it is drawn off the upper shelf and spread over the lower shelf or bottom of the furnace, where it is exposed to a greater heat for a certain time, during which it is well stirred, for the purpose of exposing all the parts equally to the action of the heat, and at the same time the fusion of any portion of it is prevented. By this process the sulphuret of lead becomes converted partly into sulphate and partly into oxide of lead. This product of sulphate and oxide of lead is to be crushed by any ordinary means, and reduced to about the same degree of fineness as coarse sand. It is now to be combined with the ammoniacal liquors, when sulphate of ammonia and sulphuret and carbonate of lead will be produced.

The sulphate of ammonia is separated by treatment with water, and the residuary mixture of sulphide and carbonate of lead is used for the manufacture of lead compounds.

Properties.—The sulphate of ammonia obtained by either of the methods above

* Pharm. Journal, xiii. 64.

Digitized by Google

described is a colourless salt, containing, according to Mitscherlich, one equivalent of water of crystallisation. It is isomorphous with sulphate of potash.

It deliquesces by exposure to the air; 1 part dissolves in 2 parts of cold water, and 1 of boiling water. It fuses at 140° C. (284° F.), but at 280° C. (536° F.) it is decomposed, being volatilised in the form of free ammonia, sulphite, water, and nitrogen.

For the other sulphates—the sulphites and those salts which are but little used in the arts and manufactures—we refer to Watts' "Dictionary of Chemistry."

Uses.—The chief consumption of ammoniacal salts in the arts is in the form of sal ammoniac, the sulphate of ammonia being principally used as a material for the manufacture of the chloride of ammonium. It may, however, be employed directly in making ammonia-alum, or in the production of free ammonia by treatment with lime.

AMMONIUM. (NH^4) The radical supposed to exist in the various salts of ammonia. Thus NH^4O is the oxide, NH^4Cl the chloride, of ammonium. Ammonium constitutes one of the best established chemical types. See FORMULÆ, CHEMICAL.—C. G. W.

AMMONIUM, CHLORIDE OF. Commonly called SAL AMMONIAC. (*Sal ammoniac*, Fr.; *Salmiak*, Germ.) The early history of this salt is involved in much uncertainty. It would appear that the *sal ammoniacus* (ἅλς ἀμμωνιακός) of the ancients was, in fact, rock-salt. The earliest knowledge of the compound has been claimed both for the Arabians and the Egyptians; but the late Dr. Royle remarked, that "the salt must have been familiar to the Hindoos ever since they have burnt bricks, as they now do, with the manure of animals, for some may usually be found crystallised at the unburnt extremity of the kiln."

This salt is formed in the solid state by bringing in contact its two gaseous constituents, hydrochloric acid and ammonia. The gases combine with such force as to generate, not only heat, but sometimes even light. It may also be prepared by mixing the aqueous solutions of these gases, and evaporating till crystallisation takes place.

When ammoniacal gas is brought into contact with dry chlorine, a violent reaction ensues, attended by the evolution of heat and even light. The chlorine combines with the hydrogen to produce hydrochloric acid, which unites with the remainder of the ammonia, forming chloride of ammonium, the nitrogen being liberated. The same reaction takes place on passing chlorine gas into the saturated aqueous solution of ammonia.

Manufacture of Chloride of Ammonium from Camels' Dung.—In Egypt—which undoubtedly was the great seat of the manufacture of this salt from the beginning of the thirteenth to the middle of the seventeenth century, and whence all the European markets were supplied—the following is the process by which it is obtained:—

The original source was the urine and dung of the camel, which are dried by plastering them upon the walls, and burning, other fuel being very scarce in that country. A fire of this material evolves a thick smoke, charged with chloride of ammonium, part of which is condensed with the soot.

In every part of Egypt, but especially in the Delta, peasants are seen driving asses loaded with bags of that soot, on their way to the sal-ammoniac works.

Here it is extracted in the following manner:—Glass globes, coated with loam, are filled with the soot, pressed down by wooden rammers, a space of only two or three inches being left vacant, near their mouths. These globes are set in round orifices formed in the ridge of a long vault or large horizontal furnace flue. Heat is gradually applied by a fire of dry camels' dung, and it is eventually increased till the globes become obscurely red. As the chloride of ammonium is volatile at a temperature much below ignition, it rises out of the soot in vapour, and gets condensed into a cake upon the inner surface of the top of the globe. A considerable portion, however, escapes into the air; and another portion concretes in the mouth, which must be cleared from time to time by an iron rod. Towards the end, the obstruction becomes very troublesome and must be most carefully attended to and obviated, otherwise the globes would explode by the uncondensed vapours. In all cases when the subliming process approaches to a conclusion, the globes crack or split; and when they come to be removed, after the heat has subsided, they usually fall to pieces. The upper portion of the mass is separated, because to it the white salt adheres; and, on detaching the pieces of glass with a hatchet, it is ready for the market. At the bottom of each balloon a nucleus of salt remains, surrounded with fixed pulverulent matter. This is reserved, and, after being bruised, is put in along with the charge of soot in a fresh operation.

The sal ammoniac obtained by this process is dull, spongy, and of a greyish hue; but nothing better was for a long period known in commerce. Fifty years ago, it

Digitized by Google

fetched 2*s.* 6*d.* a pound; whereas now, perfectly pure sal ammoniac may be had at one-fifth of that price.

Manufacture of Sal Ammoniac from Bones and other Animal Matter.—Various animal offals develope, during their spontaneous putrefactive fermentation, or their decomposition by heat, a large quantity of free or carbonated ammonia among their volatile products. Upon this principle many sal ammoniac works have been established.—*Watts' Dictionary of Chemistry.*

The first attempts made in France to obtain sal ammoniac profitably in this manner failed. A very extensive factory of the kind, which experienced the same fate, was under the superintendence of the celebrated Baumé. It was established at Gravelle, near Charenton, and caused a loss to the shareholders in the speculation of upwards of 400,000 francs, which result closed the concern in 1787. For 10 years after that event, all the sal ammoniac consumed in France was imported from foreign countries. Since then the two works of MM. Payen and Pluvinet were mounted, and seem to have been tolerably successful. Coal soot was, prior to the introduction of the gas works, a good deal used in Great Britain for obtaining sal ammoniac.

In France, bones and other animal matters are distilled in large iron retorts for the manufacture of both animal charcoal and sal ammoniac.

"The annexed numbers show the produce of a French manufactory of ammonia and its salts, from the distillation of bones and other matters.

"The materials were—

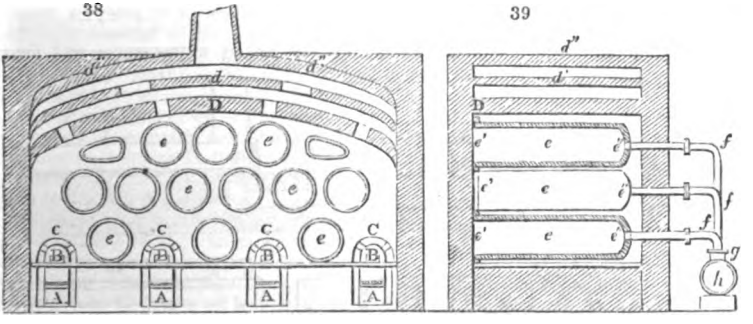
46,754	tons	of bones of various kinds.
30	„	silk waste and old leather
11½	„	sulphuric acid.
80	„	chloride of sodium.
2¾	„	sulphate of lime.

and the produce was—

2,400	tons	of animal charcoal.
44	„	chloride of ammonium.
100	„	sulphate of soda.
4	„	liquor ammonia.
and 25	„	sulphate of ammonia."

—*Muspratt.*

These retorts are iron cylinders, two or three in diameter and six feet long. *Figs.*



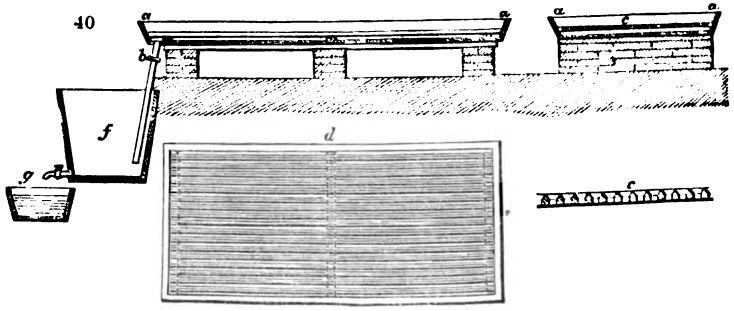
38 and 39 show the form of the furnace, and the manner in which the cylinders are arranged, the first being a longitudinal, the second a transverse section of it. A, the ashpits under the grates; B, the fire-places, arched over at top; C, the vault or bench of fire-bricks, perforated inside with eight flues for distributing the flame; D, a great arch, with a triple voissoir D, *d''*, *d'''*, under which the retorts are set. The first arch, D, is perforated with twenty vent-holes, the second with four vent-holes, through which the flame passes to the third arch, and thence to the common chimney-stalks. The retorts are shut by the door *e'* (*fig.* 39), luted, and made fast with screw-bolts. Their other ends, *e'*, terminate in tubes, *f*, *f*, *f*, which all enter the main pipe, *h*. The condensing pipe proceeds slantingly downwards from the further end of *h*, and dips into large sloping iron cylinder immersed in cold water.

The filters used in the large sal ammoniac works in France are represented in *fig.* 40. The apparatus consists—1, of a wooden chest, *a*, lined with lead, and which is turned over at the edges; a socket of lead, *b*, soldered into the lowest part of the bottom serves to discharge the liquid; 2, of a wooden crib or grating, formed of rounded rods, as shown in the section *c*, *c*, and the plan *d*; this grating is supported

Digitized by Google

one inch at least above the bottom, and set truly horizontal, by a series of wedges; 3, of an open fabric of canvas or strong calico, laid on the grating, and secured over

40



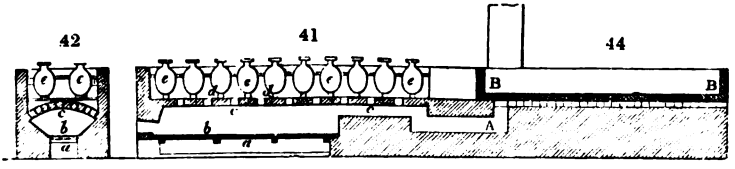
the edges so as to keep it tense. A large wooden reservoir, *f*, lined with lead, furnished with a cover, is placed under each of the filters; a pump throws back once or twice upon the filters what has already passed through. A common reservoir, *g*, below the others, may be made to communicate at pleasure with one of them by means of intermediate stopcocks.

The two boilers for evaporating and decomposing are made of lead, about one quarter of an inch thick, set upon a fire-brick vault, to protect them from the direct action of the flame. Through the whole extent of their bottoms above the vault, horizontal cast-iron plates, supported by ledges and brick compartments, compel the flame and burned air, as they issue from the arch, to take a sinuous course before they pass up the chimney. This floor of cast iron is intended to support the bottom of the boiler, and to diffuse the heat more equably. The leaden boilers are surrounded with brickwork, and supported at their edges with a wooden frame. They may be emptied at pleasure into lower receivers, called crystallisers, by means of leaden syphons and long-necked funnels.

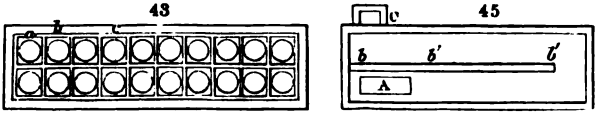
The crystallisers are wooden chests lined with lead, 15 inches deep, 3 or 4 feet broad, and from 6 to 8 feet long, and may be inclined to one side at pleasure. A round cistern receives the drainings of the mother-waters. The pump is made of lead hardened with antimony and tin.

The subliming furnace is shown in *figs* 41 and 42, by a transverse and longi-

42 41 44



43 45



tudinal section; *a* is the ashpit; *b*, the grate and fireplace; *c*, the arch above them. This arch, destined to protect the bottles from the direct action of the fire, is perforated with vent-holes, to give a passage to the products of combustion between the subliming vessels; *d*, *d*, are bars of iron, upon which the bottom of the bottles rest; *e*, stoneware bottles, protected by a coating of loam from the flame.

Fig. 43 shows the cast-iron plates, *a*, *b*, *c*, which, placed above the vaults, receive each two bottles in a double circular opening.

At the extremity of the above furnace, a second one, called the drier, *fig.* 44, receives the products of the combustion of the first at A, under horizontal cast-iron plates, and upon which the bottom of a rather shallow boiler, B, rests. After passing twice under these plates, round a longitudinal brick partition, *b*, *b'*, *b''*, the products of combustion enter the smoke chimney, C. See plan, *fig.* 45.

The boiler set over this furnace should have no soldered joints. It may be 3½ feet

Digitized by Google

broad, 9 or 10 feet long, and 1 foot deep. The concrete sal ammoniac may be crushed under a pair of edge millstones, when it is to be sold in powder.

Bones, blood, flesh, horns, hoofs, woollen rags, silk, hair, scrapings of hides and leather, &c., may be distilled for procuring ammonia. When bones are used, the residuum in the retort is bone black. The charcoal from the other substances will serve for the manufacture of prussian blue. The bones should undergo a degree of calcination beyond what the ammoniacal process requires, in order to convert them into the best bone black; but the other animal matters should not be calcined up to that point, otherwise they are of little use in the Prussian blue works. If the bones be calcined, however, so highly as to become glazed, their decolorising power on syrups is nearly destroyed. The other substances should not be charred beyond a red-brown heat.

The condensed vapours from the cylinder retorts afford a compound liquor holding carbonate of ammonia in solution, mixed with a large quantity of empyreumatic oil, which floats at top. Lest incrustations of salt should at any time tend to obstruct the tubes, a pipe should be inserted within them and connected with a steam boiler, so as to blow steam through them occasionally.

The whole liquors mixed have usually a density of 8° or 9° Baumé (1·060). The simplest process for converting their carbonate of ammonia into the chloride of ammonium is to saturate them with hydrochloric acid, to evaporate the solution in a leaden boiler till a pellicle appears, to run it off into crystallisers, and to drain the crystals. Another process is, to decompose the carbonate of ammonia, by passing its crude liquor through a layer of sulphate of lime, 3 or four inches thick, spread upon the filters, *fig.* 40. The liquor may be laid on with a pump; it should never stand higher than 1 or 2 inches above the surface of the bruised gypsum, and it should be closely covered with boards, to prevent the dissipation of the volatile alkali in the air. When the liquor has passed through the first filter, it must be pumped up on the second; or the filters being placed in a terrace form, the liquor from the first may flow down upon the second, and thus in succession. The last filter should be formed of nearly fresh gypsum, so as to insure the thorough conversion of the carbonate into sulphate. The resulting layers of carbonate of lime should be washed with a little water, to extract the sulphate of ammonia interposed among its particles. The ammoniacal liquor thus obtained must be completely saturated, by adding the requisite quantity of sulphuric acid; even a slight excess of acid can do no harm. It is then to be evaporated, and the oil must be skimmed off in the course of the concentration. When the liquid sulphate has acquired the density of about 1·160, sea salt should be added, with constant stirring, till the whole quantity equivalent to the double decomposition is introduced into the lead boiler.

The fluid part must now be drawn off by a syphon into a somewhat deep reservoir, where the impurities are allowed to subside; it is then evaporated by boiling till the sulphate of soda falls down in granular crystals, as the result of the mutual reaction of the sulphate of ammonia and chloride of sodium; while the more soluble chloride of ammonium remains in the liquor. During this precipitation, the whole must be occasionally agitated with wooden paddles; the precipitate being in the intervals removed to the cooler portion of the pan, in order to be taken out by copper rakes and shovels, and thrown into draining-hoppers, placed near the edges of the pan. The drained sulphate of soda must be afterwards washed with cold water, to extract all the adhering sal ammoniac.

The liquor thus freed from the greater part of the sulphate, when sufficiently concentrated, is to be drawn off by a lead syphon into the crystallisers, where, at the end of 20 or 30 hours, it affords an abundant crop of crystals of sal ammoniac. The mother-water may then be run off, the crystallisers set aslope to drain the salt, and the salt itself must be washed, first by a weak solution of sal ammoniac, and lastly with water. It must be next desiccated, by the apparatus *fig.* 44, into a perfectly dry powder, then put into the subliming stoneware balloons, by means of a funnel, and well rammed down. The mouth of the bottle is to be closed with a plate or inverted pot of any kind. The fire must be nicely regulated, so as to effect the sublimation of the pure salt from the under part of the bottle, with due regularity, into a white cake in the upper part. The neck of the bottle should be cleared from time to time with a long steel skewer, to prevent the risk of choking, and consequent bursting; but in spite of every precaution, several of the bottles crack almost in every operation.— *Ure.*

The pots are of variable dimensions, but those most frequently employed are about 18 inches in height in the body, and the cups about 10 or 12 inches, with a breadth of 16 inches at the widest part.

In Scotland a process somewhat similar is pursued, the salt being sublimed in cast-iron pots lined with fire-proof tiles; the condensation being effected in globular heads of green glass, with which each of the iron pots is capped.

Manufacture of Sal Ammoniac from Gas Liquor.—By far the largest quantity of the ammoniacal salts now met with in commerce is prepared from "gas liquor," the quantity of which annually produced in the metropolis alone is quite extraordinary—*one* of the London gas works producing in one year 224,800 gallons of gas liquor, by the distillation of 51,100 tons of coal; and the total consumption of coal in London for gas making is estimated at about 840,000 tons.

The principle of the conversion of the nitrogen of coal into ammonia by destructive distillation, as in the manufacture of coal gas, will be found described in connection with the processes of gas manufacture and the products produced by the destructive distillation of coal.

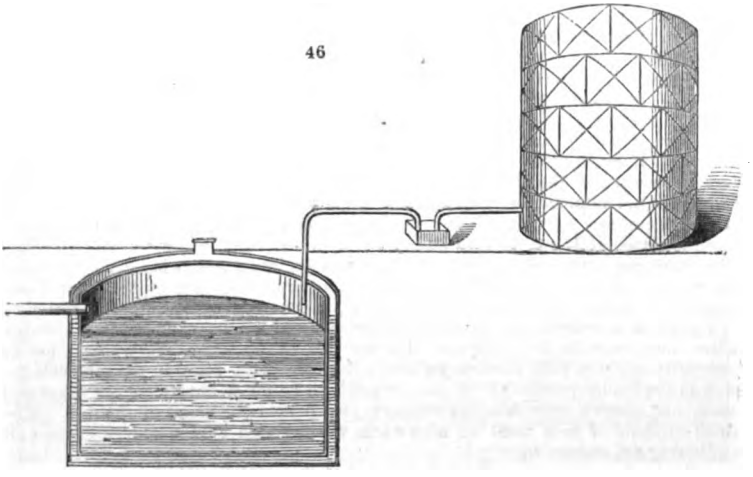
In the purification of the coal gas, the bodies soluble in water are all contained in the "gas liquor" (see COAL GAS), together with a certain quantity of tarry matter. The ammonia is chiefly present in the form of carbonate, together with certain quantities of chloride, sulphide, cyanide, and sulphocyanide of ammonium, as well as the salts of the compound ammonias.

For the purpose of preparing the chloride, if hydrochloric acid be not too costly, the liquor is saturated with hydrochloric acid — the solution evaporated to cause the salt to crystallise, and then, finally, the crude sal ammoniac is purified by sublimation.

Before treatment with the acid, the liquor is frequently distilled.

This is generally effected in a wrought-iron boiler, the liquors passing into a modification of the Coffey's still, by which the solution of ammonia is obtained freer from tar and more concentrated.

The Saturation of the Ammoniacal Liquor with the acid is generally effected by allowing the acid to flow, from a large leaden vessel in which it is held, into an under-



ground tank (*fig.* 46) containing the liquor, which is furnished with an exit tube passing into a chimney, to carry off the sulphuretted hydrogen and other offensive gases which are disengaged.

Or in other works the gas liquor is put into large tuns, and the acid lifted in gutta percha carboys by cranes, thrown into the liquor and stirred with it by means of an agitator; the offensive gases being in this case made to traverse the fire of the steam-engine.

Sometimes the vapours produced in the distillation of the crude gas liquor are passed in at the lower extremity of a column filled with coke, down which the acid trickles.

The *Evaporation of the crude Saline Solution* is generally performed in square or rectangular cast-iron vats, capable of holding from 800 to 1500 gallons. They are encased in brickwork, the heat being applied by a fire, the flue of which takes a sinuous course beneath the lining of brickwork on which the pan rests, as shown in *fig.* 47.

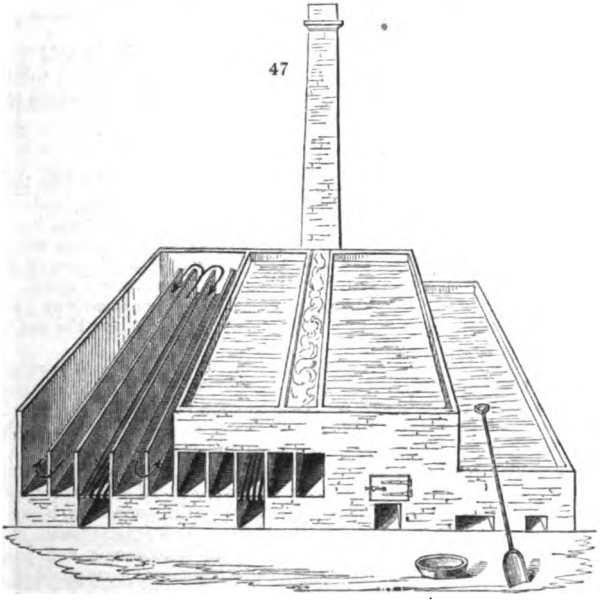
When the liquor is evaporated to a specific gravity of 1·25, it is transferred to the crystallising pans; but during the process of concentration a considerable quantity of tar separates on the surface, which must be removed, from time to time, by skimming, since it seriously impedes evaporation.

The *crystallisation*, which takes place on cooling, is performed in circular tubs,

Digitized by Google

from 7 to 8 feet wide, and 2 to 3 deep, which are generally embedded entirely or partially in the ground. To prevent the formation of large crystals, which would be

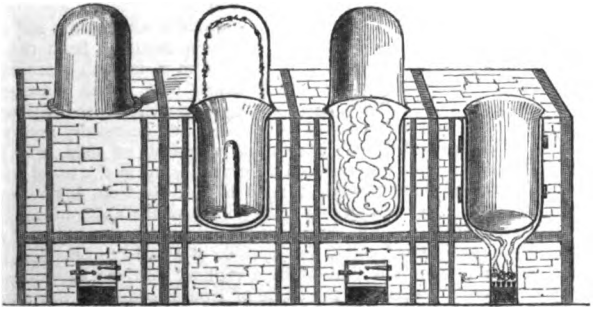
47



inconvenient in the subsequent process of sublimation, the liquor is agitated from time to time. The crude mass obtained, which is contaminated with tarry matter, free acid, and water, is next dried, by gently heating it on a cast-iron plate under a dome. The greyish-white mass remaining is now ready to be transferred to the sublimers.

4. The method of *sublimation* generally adopted in this country consists in beating down into the metal pots, shown in *fig.* 48, the charge of dry coarsely crystallised

48



sal ammoniac. These pots are heated from below and by flues round the sides. The body of the subliming vessel is of cast iron, and the lid usually of lead, or, less frequently, iron. There is a small hole at the top, to permit the escape of steam; and great attention is requisite in the management of the heat, for if it be applied too rapidly a large quantity of sal ammoniac is carried off with the steam, or even the whole apparatus may be blown up; whilst, if the temperature be too low, the cake of sal ammoniac is apt to be soft and yellow.

The sublimation is never continued until the whole of the salt has been volatilised, since the heat required would decompose the carbonaceous impurities, and they, emitting volatile oily hydrocarbons, diminish the purity of the product. In consequence

Digitized by Google

of this incomplete sublimation, a conical mass (shown in the *fig.* 48) is left behind, called the "yolk." After cooling, the dome of the pot is taken off and the attached cake carefully removed. This cake, which is from 3 to 5 inches thick, is nearly pure, only requiring a little scraping, where it was in contact with the dome, to fit it for the market.

Modifications of the Process. — If, as is often the case, sulphuric acid is cheaper or more accessible than hydrochloric, the gas liquor is neutralised with sulphuric acid, and then the sulphate of ammonia thus obtained is sublimed with common salt (*chloride of sodium*), and thus converted into sal ammoniac.

$$NH^2O\ SO^3 + NaCl = NH^4\ Cl + NaOSO^3.$$

Mr. Croll has taked out a patent for converting crude ammonia into the chloride, by passing the vapours evolved in the first distillation through the crude chloride of manganese, obtained, as a bye product in the preparation of chlorine, for the manufacture of chloride of lime: crude chloride of iron may be used in the same way.

Mr. Laming patented in July, 1843, the substitution of a solution of chloride of calcium for treating the crude gas liquor, instead of the mineral acids. Mr. Hills, August, 1846, proposed chloride of magnesium for use in the same way; and several other patents have been taken out by both these gentlemen, for the use of various salts in this way.

Manufacture of Sal Ammoniac from Guano.— Mr. Young took out a patent, November 11th, 1841, in which he describes his method of obtaining ammonia and its salts from guano. He fills a retort, placed vertically, with a mixture of two parts by weight of guano, and one part by weight of hydrate of lime. These substances are thoroughly mixed by giving a reciprocating motion to the agitator placed in the retort; a moderate degree of heat is then applied, which is gradually increased until the bottom of the retort becomes red-hot. The ammoniacal gas thus given off is absorbed by water in a condenser, whilst other gases, which are given off at the same time, being insoluble in water, pass off. Solutions of carbonate, bicarbonate, or sesquicarbonate of ammonia are produced, by filling the condenser with a solution of ammonia, and passing carbonic acid through it. A solution of chloride of ammonium or sulphate of ammonia is obtained by filling the condenser with diluted hydrochloric or sulphuric acid, and passing the ammonia through it as it issues from the retort.

Dr. Wilton Turner obtained a patent, March 11th, 1844, for obtaining salts of ammonia from guano. The following is his method of obtaining chloride of ammonium in conjunction with cyanogen compounds:— The guano is subjected to destructive distillation in close vessels, at a low red heat during the greater part of the operation; but this temperature is increased towards the end. The products of distillation are collected in a series of Woolfe's bottles, by means of which the gases evolved during the operation may be made to pass two or three times through water, before escaping into the air. These products consist of carbonate of ammonia, hydrocyanic acid, and carburetted hydrogen, the first two of which are rapidly absorbed by the water, with the formation of a strong solution of cyanide of ammonium and carbonate of ammonia. After the ammoniacal solution has been removed from the Woolfe's apparatus, a solution of protochloride of iron is added to it, in such quantities as will yield sufficient iron to convert the latter into Prussian blue, which is formed on the addition of hydrochloric acid in sufficient quantity to neutralise the free ammonia; the precipitate thus formed is now allowed to subside, and is carefully separated from the solution, and by being boiled with a solution of potash or soda, will yield the ferrocyanide of the alkali, which is obtained by crystallising in the usual way. The solution (after the removal of the precipitate) should be freed from any excess of iron it may contain, by the careful addition of a fresh portion of the ammoniacal liquor, by which means the oxide of iron will be precipitated, and a neutral solution of ammonia obtained. When the precipitated oxide and cyanide of iron have subsided, the solution of chloride of ammonium is drawn off by a syphon, and the sal-ammoniac obtained from it by the usual processes; the oxide of iron is added to the ammoniacal solution next operated upon.

If sulphate of iron and sulphuric acid are used, sulphate of ammonia is the ammoniacal salt produced, the chemical changes and operations being similar to the above.

Since the greater part of the nitrogen present in guano exists in the state of ammoniacal salts which are decomposed at a red heat, nearly the whole of the ammonia which it is capable of yielding is obtained by this method; still there cannot be a doubt that the conversion of the urea, uric acid, and other nitrogenised organic bodies into ammonia, is greatly facilitated by mixing the guano with lime before heating it, as in Mr. Young's process.

Manufacture of Sal Ammoniac from Urine. — The urea in the urine of man and other animals is extremely liable to undergo a fermentative decomposition in the

Digitized by Google

presence of the putrefiable nitrogenous matters always present in this excrement, by which it is converted into carbonate of ammonia.

By treating stale urine with hydrochloric acid, sal ammoniac separates on evaporation.

Properties.—Chloride of ammonium (or sal ammoniac) usually occurs in commerce, in fibrous masses of the form of large hemispherical cakes with a round hole in the centre, having, in fact, the shape of the domes in which it has been sublimed. By slowly evaporating its aqueous solution, the salt may occasionally be obtained in cakes nearly an inch in height; but it generally forms feathery crystals, which are composed of rows of minute octahedra, attached by their extremities. Its specific gravity is 1·45, and by heating it sublimes without undergoing fusion. It has a sharp and acrid taste, and one part dissolves in 2·72 parts of water at 65° F., or in an equal weight of water at 212° F.

It is recognised by its being completely volatile on heating, giving a white curdy precipitate of chloride of silver on the addition of nitrate of silver to its aqueous solution, and by the copious evolution of ammonia on mixing it with lime, as well as the production of the yellow precipitate of the double chloride of ammonium and platinum ($NH^4Cl, PtCl^2$) on the addition of bichloride of platinum.

Impurities.—In the manufacture of chloride of ammonium, if the purification of the liquor be not effected before crystallising the salt, some traces of protochloride of iron are generally present, and frequently a considerable proportion. Even when the salt is sublimed, the chloride of iron is volatilised together with the chloride of ammonium, and appears to exist in the salt in the form of a double compound (probably of $FeCl, NH^4Cl$, analogous to the compound which chloride of ammonium forms with zinc and tin) 140; and this not only in the brown seams of the cake, but likewise in the colourless portion. This accounts for the observation so often made in the laboratory, that a solution of sal ammoniac, which, when recently prepared, was perfectly transparent and colourless, becomes gradually red from the peroxidation of the iron and its precipitation in the form of sesquioxide.

It is in consequence of the existence of the iron in the state of this double salt, that Wurtz found that chloride of ammonium containing iron in this form gave no indications of its presence by the usual reagents until after the addition of nitric acid; and it is curious that there likewise exists a red compound of this class in which the iron exists in the state of perchloride similarly marked, in fact as NH^4Cl, Fe^2Cl^3.

A very simple method of removing the iron, suggested by Mr. Brewer, consists in passing a few bubbles of chlorine gas through the hot concentrated solution of the salt, by which the protochloride of iron is converted into the perchloride.

$$2FeCl + Cl = Fe^2Cl^3.$$

The free ammonia always present in the solution decomposes this perchloride with precipitation of sesquioxide, and formation of an additional quantity of sal ammoniac.

$$Fe^2Cl^3 + 3NH^4O = Fe^2O^3 + 3NH^4Cl.$$

The sesquioxide of iron, which is of course present in the form of a brown hydrate, is filtered off or separated by decantation, and a perfectly pure solution is obtained.

The only precaution necessary is to avoid passing more chlorine than is requisite to peroxidise the iron, since the ammonia salt itself will be decomposed with evolution of nitrogen, and the dangerously explosive body, chloride of nitrogen, may result from the union of the liberated nitrogen with chlorine.

Uses.—The most important use of sal ammoniac in the arts is in joining iron and other metals, in tinning, &c. It is also extensively used in the manufacture of ammonia-alum, which is now largely employed in the manufacture of mordants instead of potash-alum. A considerable quantity is also consumed in pharmacy.

Sal ammoniac is one of those salts which possesses, in a high degree, the property of producing cold whilst dissolving in water; it is, therefore, a common constituent of frigorific mixtures. See FREEZING MIXTURES.

AMMONIUM, SULPHIDES OF. When sulphuretted hydrogen gas is passed into a solution of ammonia in excess, it is converted into the double sulphide of ammonium and hydrogen—or, as it is frequently called, the hydrosulphate of sulphide of ammonium—NH^4S, HS.

This solution is extensively employed as a re-agent in the chemical laboratory, for the separation of those metals the sulphides of which are soluble in acids—viz., nickel, cobalt, manganese, zinc, and iron, which are precipitated by this re-agent in alkaline solutions.

By exposure to the air, the hydrosulphuric acid which it contains is decomposed, the hydrogen being oxidised and converted into water, whilst the liberated sulphur

Digitized by Google

is dissolved by the sulphide of ammonium, forming the bisulphide, or even higher sulphide.

This solution of the polysulphide of ammonium is a valuable re-agent for dissolving the sulphides of certain metals, such as tin, antimony, and arsenic, the sulphides of which play the part of acids and form salts with the sulphide of ammonium.

By this deportment with sulphide of ammonium, these metals are separated, both on the small scale in the laboratory and also on the large scale, from the sulphides of those metals—such as lead, copper, mercury, &c.—the sulphides of which are insoluble in sulphide of ammonium.

The higher sulphides, viz., the tersulphide, $NH^4 S^3$, and the pentasulphide, $NH^4 S^5$,—are bodies of purely scientific interest. They are obtained by distilling the corresponding sulphides of potassium with sal ammoniac.

All the sulphides of ammonium are soluble in water without decomposition.

Ammonia combines with all the inorganic and organic acids, but for an account of these compound bodies we must refer to Watts' "Dictionary of Chemistry," as they have but few applications in the arts and manufactures.

AMORPHOUS. (*Privative*, ἀ, destitute of; μορφή, shape: *without shape.*) Said of mineral and other substances which occur in forms not easy to be defined. This term may be regarded as the opposite of crystalline. Some elements exist in both the crystalline and the amorphous states, as carbon, which is amorphous in charcoal, but crystalline in the diamond.

The peculiarities which give rise to these conditions—evidently depending upon molecular forces which have not yet been defined—present one of the most fertile fields for study in the range of modern science.

AMYGDALIN. ($C^{40} H^{27} NO^{22} + 6HO$.) A peculiar substance, existing ready-formed in bitter almonds, the leaves of the cherry-laurel, the kernels of the plum, cherry, peach, and the leaves and bark of *Prunus padus*, and in the young sprouts of the *P. domestica*. It is also found in the sprouts of several species of *Sorbus*, such as *S. aucuparia*, *S. torminalis*, and others of the same order. To prepare it, the bitter almonds are subjected to strong pressure between hot plates of metal. This has the effect of removing the bland oil known in commerce as almond oil. The residue, when powdered, forms almond meal. To obtain amygdalin from the meal, the latter is extracted with boiling alcohol of 90 or 95 per cent. The tincture is to be passed through a cloth and the residue pressed, to obtain the fluid mechanically adherent to it. The liquids will be milky, owing to the presence of some of the oil. On keeping the fluid for a few hours, it may be separated by pouring off, or by means of a funnel, and so obtained clear. The alcohol is now to be removed by distillation, the latter being continued until five-sixths have come over. The fluid in the retort, when cold, is to have the amygdalin precipitated from it by the addition of half its volume of ether. The crystals are to be pressed between folds of filtering paper, and recrystallised from concentrated boiling alcohol. As thus prepared, it forms pearly scales, very soluble in hot alcohol, but sparingly when cold; it is insoluble in ether, but water dissolves it readily and in large quantity. The crystals contain six atoms of water of crystallisation. Most persons engaged in chemical operations have noticed, when using almond meal for the purpose of luting, that, before being moistened with water, it has little odour, and what it has is of an oily kind; but, after moistening, it soon acquires the powerful and pleasant perfume of bitter-almond oil. This arises from a singular reaction taking place between the amygdalin and the vegetable albumen or emulsin. The latter merely acts as a ferment, and its elements in no way enter into the products formed. The decomposition, in fact, takes place between one equivalent of amygdalin and four equivalents of water; the product being one equivalent of bitter-almond oil, two equivalents of grape-sugar, and one of prussic acid. Or, represented in symbols:—

$$\underbrace{C^{40} H^{27} NO^{22}}_{\text{Amygdalin.}} + 4HO = \underbrace{C^{14} H^6 O^2}_{\text{Bitter-almond oil.}} + \underbrace{C^2 HN}_{\text{Prussic acid.}} + \underbrace{2C^{12} H^{12} O^{12}}_{\text{Grape-sugar.}}.$$

In preparing amygdalin, some chemists add water to the residue of the distillation of the tincture, and then yeast, in order to remove the sugar present, by fermentation, previous to precipitating with ether: the process thus becomes much more complex, because it is necessary to filter the fermented liquid, and concentrate it again by evaporation, before precipitating out the amygdaline.

The proof that the decomposition which is experienced by the bitter almond cake, when digested with water, is owing to the presence of the two principles mentioned, rests upon the following considerations. If the marc, or pressed residue of the bitter almond, be treated with boiling water, the emulsine — or vegetable albumen — will

Digitized by Google

become coagulated, and incapable of inducing the decomposition of the amygdalin. It is only the bitter almond which contains amygdalin; the sweet variety is, therefore, incapable of yielding the essence by fermentation. But sweet almonds resemble the bitter in containing emulsin; and it is exceedingly interesting—as illustrating the truth of the explanation given above—that if a little amygdalin be added to an emulsion of sweet almonds, the bitter-almond essence is immediately formed. A temperature of 100° is the most favourable for the digestion.—C. G. W.

AMYLAMINE. (C^{10} H^{13} N.) A volatile organic base formed on the ammonia type. It is, in fact, ammonia in which one equivalent of hydrogen is replaced by the radical amyl, C^{10} H^{11}. It may be produced artificially by several processes: 1. By boiling cyanate of amyl with potash. 2. By the action of potash on amylic urea. 3. By the action of iodide of amyl on ammonia. It is contained among the organic bases of bone oil, and is said to be obtained in a state of purity from horn and leucine by destructive distillation. It was discovered by Wurtz, to whom we are indebted for the first and second modes of preparation. The third process was discovered by Hofmann. It has been recently found that when flannel is distilled with potash, amylamine comes over with butylamine.

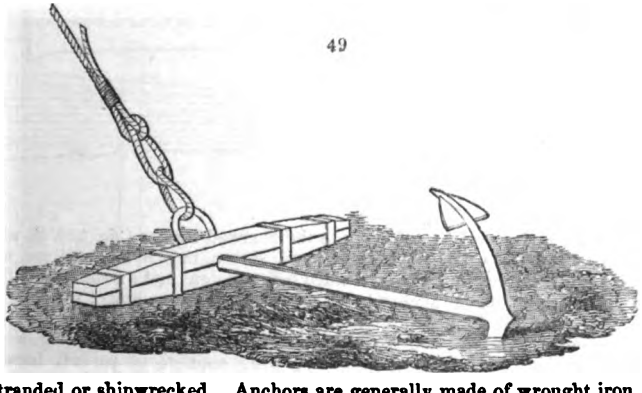
Amylamine, in a state of purity, is a colourless mobile fluid of an extremely burning taste. Its density is 0·750 at 64°. It boils at 203° F.—C. G. W.

AMYLENE. This hydrocarbon (C^{10} H^{10}) is produced by the dehydration of amylic alcohol by sulphuric acid; also by the dry distillation of amyl-sulphate of calcium. It is a colourless thin liquid, with a faint offensive odour. It has been tried as a substitute for chloroform without success.

AMYLUM MANDIOCÆ. Mandioca or Cassava starch.

ANALYSIS. A chemical term which is employed to signify the art of resolving a compound substance into its constituent parts. Every manufacturer should so study this art, in the proper treatises and schools of chemistry, as to enable him properly to understand and regulate his business. It is used also in Mechanics.–SeeWatts' "Dictionary of Chemistry."

ANCHOR. (*Ancre*, Fr.; *Anker*, Germ.) An iron hook, of peculiar construction and of considerable weight and strength, for enabling a ship to lay hold of the ground, and fix itself in a certain situation by means of a rope called the cable. The necessity for securing boats, canoes, or ships in a certain position, has led to the adoption of anchors, of some description, amongst every nation dwelling upon the shores of seas, lakes, or rivers. They were often of the rudest description. We are informed that the Greeks at first used stone anchors, but that they subsequently employed instruments of iron, having one two and three teeth, which were not apparently very different from those we now employ. The anchors which are used by many of the races inhabiting the shores of the Indian ocean are made of the so-called "iron-wood," which is so dense that it sinks in sea-water. The anchor is an instrument of the greatest importance to the navigator, since upon its taking and keeping hold depends his safety upon many occasions, especially near a lee shore, where he might be other-



wise stranded or shipwrecked. Anchors are generally made of wrought iron, except among nations who cannot work this metal well, and who therefore use copper. The mode in which an anchor operates will be understood from inspection of *fig.* 49, where, from the direction of the strain, it is obvious that the anchor cannot move without ploughing up the ground in which its hook or fluke is sunk. When this, however, unluckily takes place, from the nature of the ground, from the mode of insertion of

Digitized by Google

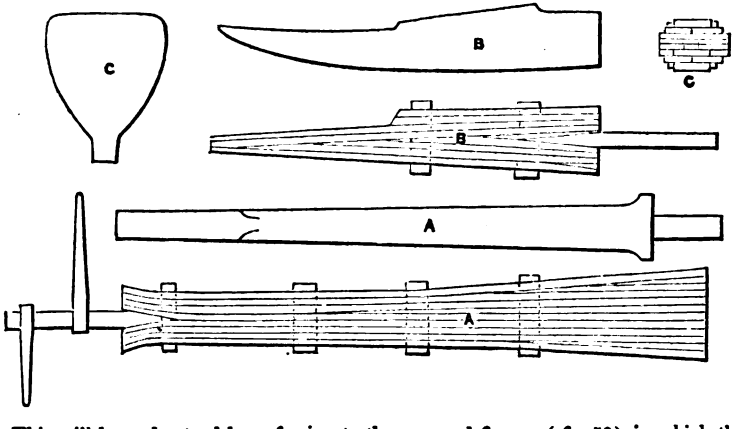
the anchor, or from the violence of the winds or currents, it is called *dragging the anchor*. When the hold is good, the cable or the buried arm will sooner break than the ship will drive. Anchors are of different sizes, and have different names, according to the purposes they serve; thus there are *bower*, *stream*, and *kedge anchors*. Ships of the first class have seven anchors, and smaller vessels, such as brigs and schooners, three.

The metal employed for anchors of wrought iron is known as "scrap iron," and for the best anchors, such as Lenox's, they also use good "Welsh mine iron."

It is not practical, without occupying more space than can be afforded, to describe in detail the manufacture of an anchor. It does not, indeed, appear desirable that we should do so, since it is so special a form of mechanical industry, that few will consult this volume for the sake of learning to make anchors. The following will therefore suffice. The anchor smith's forge consists of a hearth of brickwork, raised about 9 inches above the ground, and generally about 7 feet square. In the centre of this is a cavity for containing the fire. A vertical brick wall is built on one side of the hearth, which supports the dome, and a low chimney to carry off the smoke. Behind this wall are placed the bellows, with which the fire it urged; the bellows being so placed that they blow to the centre of the fire. The anvil and the crane by which the heavy masses of metal are moved from and to the fire are adjusted near the hearth. The *Hercules*, a kind of stamping machine, or the steam hammer, need not be described in this place.

To make the anchor, bars of good iron are brought together to be faggoted; the number varying with the size of the anchor. The faggot is kept together by hoops of iron, and the whole is placed upon the properly arranged hearth, and covered up by small coals, which are thrown upon a kind of oven made of cinders. Great care and good management is required to keep this temporary oven sound during the combustion;—a smith strictly attends to this. When all is arranged, the bellows are set to work, and a blast urged on the fire; this is continued for about an hour, when a good welding heat is obtained. The mass is now brought from the fire to the anvil, and the iron welded by the hammers. One portion having been welded, the iron is returned to fire, and the operation is repeated until the whole is welded into one mass.

50



This will be understood by referring to the annexed figures (*fig.* 50), in which the bars for the shanks, A A, and the arms, B B, are shown, in plan and sections, as bound together, and their shapes after being welded before union; and C C represents the palm.

The different parts of the anchor being made, the arms are united to the end of the shank. This must be done with great care, as the goodness of the anchor depends entirely upon this process being effectively performed. The arms being welded on, the ring has to be formed and welded. The ring consists of several bars welded together, drawn out into a round rod, passed through a hole in the shank, bent into a circle, and the ends welded together. When all the parts are adjusted, the whole anchor is brought to a red heat, and hammered with lighter hammers than those used for welding, the object being to give a finish and evenness to the surface.

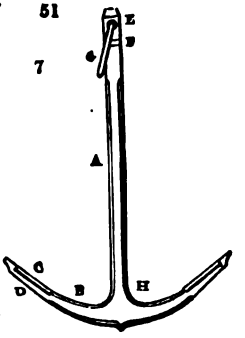
The toughest iron which can be procured should be used in the manufacture of an anchor, upon the strength of which both the security of valuable lives and much property depends.

Digitized by Google

The manufacture of anchors requires great knowledge of the structure of iron, and skill in the art of working it. The various parts of an anchor are thus named: — In *fig.* 51, A is the *shank*; B, the *arm* or *fluke*; C, the *palm*; D, the *blade*; E, the *square*; F, the *nut*; G, the *ring*; H, the *crown*,—the proportional weights of the several parts being as follows: —

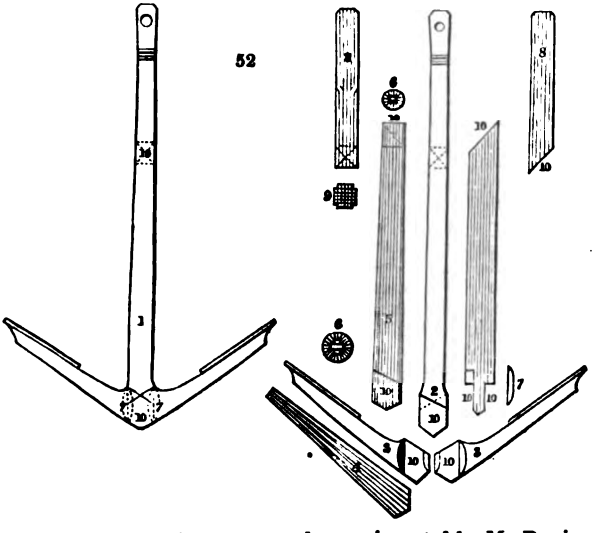
The shank	- - -	$\frac{3}{10}$ths of the whole.
Each arm	- - -	$\frac{2}{10}$ths "
Two palms	- - -	$\frac{1}{10}$th "
Stock	- - -	$\frac{1}{5}$th "
Shackle	- - -	$\frac{1}{13}$th "

51



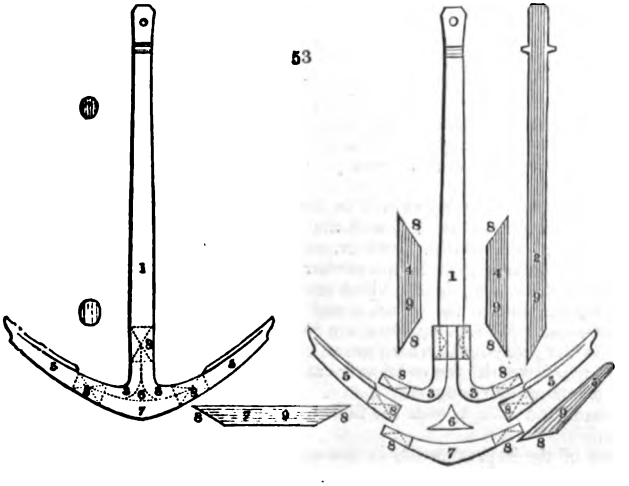
The following drawings (*fig.* 52) show an anchor on the old plan and the dissected parts of which it is composed;—

52



and the annexed (*fig.* 53), the patent anchor as invented by Mr. Perring, with its several parts dissected as before:—

53



Digitized by Google

Perring's improved anchor was a very ingenious one. The bars and half the breadth of the anchor are first welded separately, and then placed side by side, when the upper half is worked into one mass, while the lower part is left disunited, but it has carrier iron bars, or *porters*, as these prolongation rods (3, 3, *fig.* 53) are commonly called, welded to the extremity of each portion. The lower part is now heated and placed in the clamping machine, which is merely an iron plate firmly bolted to a mass of timber, and bearing upon its surface four iron pins. One end of the crown is placed between the first of these pins, and passed under an iron strap; the other end is brought between the other pins, and is bent by the leverage power of the elongated rods or porters.

Thus a part of the arm being formed out of the crown gives much greater security when a true union of fibres is effected, than when the junction was made merely by a short scarf.

The angular opening upon the side opposite is filled with the *chock*, formed of short iron bars placed upright. When this has been firmly welded, the truss-piece is brought over it. This piece is made of plates similar to the above, except that their edges are here horizontal. The truss-piece is half the breadth of the arm; so that, when united to the crown, it constitutes, with the other parts, the total breadth of the arms at those places.

The shank is now shut upon the crown; the square is formed, and the nuts welded to it; the hole is punched out for the ring, and the shank is then fashioned.

The blade is made much in the way above described. In making the palm, an iron rod is first bent into the approximate form, notching it so that it may more readily take the desired shape. To one end a *porter* rod is fastened, by which the palm is carried and turned round in the fire during the progress of the fabrication. Iron plates are next laid side by side upon the rod, and the joint at the middle is broken by another plate laid over it. When the mass is worked, its under side is filled up by similar plates, and the whole is completely welded; pieces being added to the sides, if necessary, to form the angles of the palm. The blade is then shut on to the palm, after which the part of the arm attached to the blade is united to that which constitutes the crown. The smith-work of the anchor is now finished.

The junction—or shutting on, as the workmen call it—of the several members of an anchor is effected by an instrument called a Hercules, which is merely a mass of iron raised to a certain height, between parallel uprights, as in the pile-engine or vertical ram, and let fall upon the metal previously brought to a welding heat.

The end of the shank is squared to receive and hold the stock steadily and keep it from turning. To prevent it shifting along, there are two knobs or tenon-like projections. The point of the angle H, between the arms and the shank, is sometimes called the throat. The arm, B C, generally makes an angle of 56° with the shank A; it is either round or polygonal, and about half the length of the shank.

The *stock* of the anchor (*fig.* 49) is made of oak. It consists of two beams which embrace the *square*, and are firmly united by iron bolts and hoops, as shown in the figure. The stock is usually somewhat longer than the shank, has in the middle a thickness about one-twelfth of its length, but tapers at its under side to nearly one-half this thickness at the extremities.

An ingenious form of anchor was made the subject of a patent, by Lieutenant Rodger, of the Royal Navy, in 1828, and was afterwards modified by him in a second patent, obtained in August, 1829. The whole of the parts of the anchor are to be bound together by means of iron bands or hoops, in place of bolts or pins.

Fig. 54 is a side view of a complete anchor, formed upon his improved construction, and *fig.* 55 a plan of the same; *fig.* 56, an end view of the crown and flukes, or arms; *fig.* 57 represents the two principal iron plates, *a a*, of which the shank is constructed, but so as to form parts of the stump-arms to which the flukes are to be connected.

The crown piece is to be welded to the stump-piece, *c c*, *fig.* 57, as well as to the end, *l*, of the centre-piece, *h h*, and the scarfs, *m m*, are to be cut to receive the arms or flukes. Previously, however, to uniting the arms or flukes to the stump-arms, the crown and throat of the anchor are to be strengthened, by the application of the crown slabs, *n n*, *fig.* 57, which are to be welded upon each side of the crown, overlapping the end of the pillar, *h*, and the throat or knees of the stump-arms and the crown-piece. The stump-arms are then to be strengthened in a similar manner, by the thin flat pieces, *p p*, which are to be welded upon each side. The palms are united to the flukes in the usual way, and the flukes are also united to the stump-arms by means of the long scarfs, *m m*. When the shank of the anchor has been thus formed, and united with the flukes, the anchor-smith's work may be said to be complete.

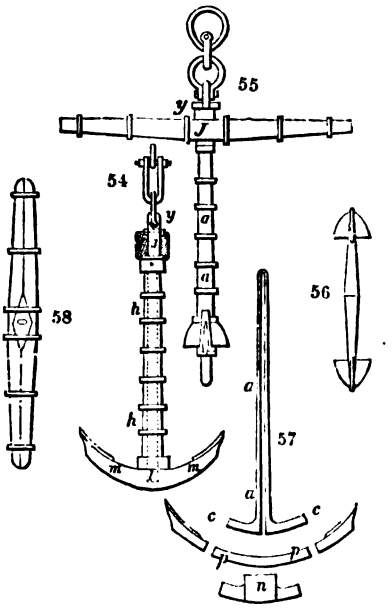
Another of the improvements in the construction of anchors, claimed under this

Digitized by Google

patent, consists in a new method of affixing the stock upon the shank of the anchor, which is effected in the following manner: in *fig.* 54 the stock is shown affixed to the anchor; in *fig.* 57 it is shown detached. It may be made either of one or two pieces of timber, as shall be found most convenient. It is, however, to be observed that the stock is to be completed before fitting on to the shank. After the stock is shaped, a hole is to be made through the middle of it, to fit that part of the shank to which it is to be affixed. Two stock plates are then to be let in, one on each side of the stock, and made fast by counter-sunk nails and straps, or hoops; other straps or hoops of iron are also to be placed round the stock, as usual.

In place of nuts, formed upon the shank of the anchor, it is proposed to secure the stock by means of a hoop and a key, shown above and below J, in *fig.* 55. By this contrivance, the stock is prevented from going nearer to the crown of the anchor than it ought to do, and the key prevents its from sliding towards the shackle.

Since fitting the stock to the shank of an anchor by this method prevents the use of a ring, as in the ordinary manner, the patentee says that he in all cases substitutes a shackle for the ring, and which is all that is required for a chain cable; but when a hempen cable is to be used, he connects a ring to the usual shackle, by means of a joining shackle, as in *figs.* 54 and 55. The stock is shown in *fig.* 58.



Mr. Rodger proposes, under another patent, dated July, 1833, to alter the size and form of the palms; having found from experience that anchors with small palms will not only hold better than with large ones, but that the arms of the anchor, even without any palms, have been found to take more secure hold of the ground than anchors of the old construction of similar weight and length. He has accordingly fixed upon one-fifth of the length of the arm, as a suitable proportion for the length or depth of the palm. He makes the palms, also, broader than they are long or deep.

Previously to the introduction of Lieutenant Rodger's small-palmed anchor, ships were supplied with heavy, cumbersome contrivances with long shanks and broad palms extending half-way up the flukes. So badly were they proportioned, that it was no uncommon thing for them to break in falling on the bottom, particularly if the ground was rocky. But, if once firmly imbedded in stiff holding ground, there was considerable difficulty in breaking them out. The introduction of the small palm, therefore, forms an important era in the history of anchors.

The next important introduction was Porter's anchor, with movable flukes or arms. One grand object sought to be attained here, was the prevention of fouling by the cable. It was considered, also, that as great injury was frequently occasioned by a ship grounding on her anchor, the closed upper arm would remedy the evil. It was found, however, that the anchor would not take the ground properly as at first constructed, and hence the "shark's fin" upon the outside of each fluke.

Rodger's invention was for some time viewed with distrust; but, from time to time, improvements were introduced, until the patent, which gained the Exhibition prize, was brought out. On this the jurors reported as follows:—

"Many remarkable improvements have been recently made by Lieutenant Rodger, R.N., insuring a better distribution of the metal in the direction of the greatest strains. The palm of the anchor, instead of being flat, presents two inclined planes, calculated for cutting the sand or mud instead of resisting perpendicularly; and the consequence is, that these new anchors hold much better in the ground. The committee of Lloyd's—so competent to judge of every contrivance likely to preserve ships—have resolved to allow for the anchors of the ships they insure a sixth less weight if made according to the plan of Lieutenant Rodger."

The original Porter's anchor has also undergone considerable modification; and, under the name of "Trotman's anchor," has now a conspicuous place.

Digitized by Google

Another invention is that of Mitcheson's, which, in form and proportions, strongly resembles Rodger's; but the palm is that adopted in Trotman's, or Porter's anchor. It is a trifle longer in the shank than Rodger's, and has a peculiar stock, which—although original in its form—lacks originality in its design, since Rodger had previously introduced a plan for an iron stock to obviate the weakness caused by making a hole for the stock to pass through. Mr. Lenox was the inventor of an anchor which differed somewhat from the Admiralty's anchor—a modification of Rodger's—in being shorter in the shank and thicker in the flukes, the palms being spade-shaped. Mr. J. Aylen, the Master-Attendant of Sheerness Dockyard, modified the Admiralty's anchor. Instead of the inner part of the fluke, from the crown to the pea, being rounded, as in the Admiralty plan, or squared as in Rodger's and Mitcheson's, it is hollowed. An American anchor, known as Isaac's, has a flat bar of iron from palm to palm, passing the shank elliptically on both sides; and from the end of the stock to the centre of the shank two other bars are fixed to prevent its fouling.

With the anchors thus briefly described the Admiralty ordered trials to be made at Woolwich, and at the Nore. The results of those trials—the particulars of which need not be given here—were, that Mitcheson's, Trotman's, Lenox's, and Rodger's were selected as the best.

A competent authority, writing in the *United Service Gazette*, says:—"The general opinion deduced from the series of experiments is, that although Mitcheson's has been so successful, the stock is not at present seaworthy. Trotman's has come out of the trial very successfully, but the construction is too complicated to render it a good working anchor. When once in the ground, its holding properties are very superior; in fact, a glance at its grasp will show that it has the capabilities of an anchor of another construction one-fifth larger. There are, however, drawbacks not easily to be overcome. Its taking the ground is more precarious than with other anchors; and if a ship should part her cable, it would scarcely be possible to sweep the anchor. It is also an awkward anchor to fish and to stow. Yet there are other merits which render it, upon the whole, a most valuable invention, and no ship should go to sea without one. *Of Lenox's, it is sufficient to say that it has been found equal to, and that it has gained an advantage over, Rodger's*; but so strong is the professional feeling in favour of the latter, that it will ever remain a favourite. Our recommendation would be thus:—Lenox and Rodger for bower anchors, Mitcheson for a sheet, and Trotman for a spare anchor."

The following Table gives at one view the results of the experiments made by the Admiralty upon breaking the trial anchors, and the time occupied upon each experiment:—

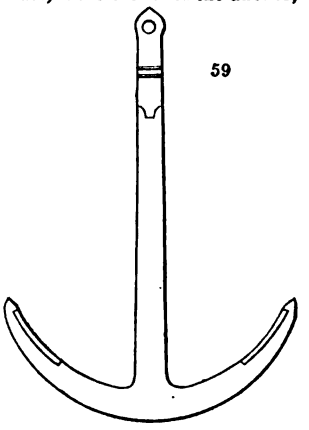
Anchors.	Weight.	Proof-strain.	First Crack.	Broke.	Time in Breaking.
	Cwts. qrs. lbs.	Tons.	Tons.	Tons.	Minutes.
Lieut. Rodger's - -	19 0 8	19⅞	45	73½	21
Brown and Lenox's -	20 3 14	21½	44½	47	7
Isaac's - - -	21 0 14	21½	58	63	10
Trotman's - - -	21 1 10	21⅞	51	53½	18
Honiball's - - -	20 3 7	21¼	54	75½	42
Admiralty's - -	20 2 6	21¼	40	56½	26
Aylen's - - -	21 1 0	21¾	44	47½	6

The history of the introduction of Lenox's anchors to the British navy was as follows:—

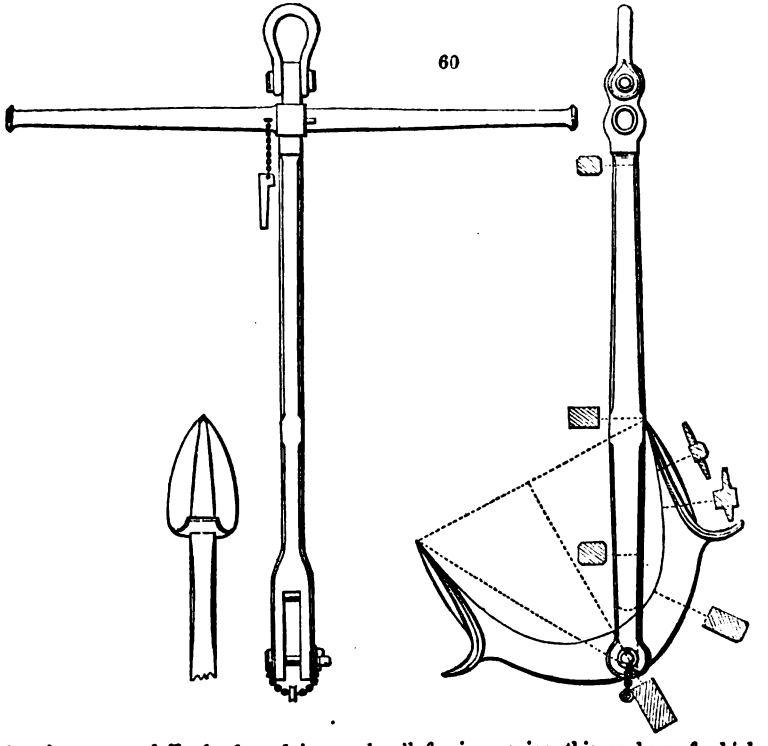
After sundry attempts to induce the Admiralty to give up entirely the use of hempen cable anchors, in consequence of their breaking when applied to chain cables, Mr. Lenox, in 1832, was permitted to alter some of the old anchors to such proportions and shape as would enable them to stand a proof-strain upon the machine in Woolwich Dockyard. It was found, as previously apprehended and asserted, that from the inequality of material in the old anchors, not above one in three was successfully altered, and Mr. Lenox was ordered to supply new anchors, which were proved, and then approved of. This state of things continued until 1838, when Mr. Lenox was requested to reconsider and complete the shape and proportions of anchors for the navy, with a view to a contract being given out for the supply of such anchors to the service. Then was constructed the shape called the "Admiralty," or "Sir William Parker's Anchor" (Sir William being then Store Lord). Mr. Lenox suggested to Sir William the doing away with every sharp edge and line in an anchor, and adopting the smooth long-oval (in the section) for the general shape of

Digitized by Google

shank and arm. This was approved of by Sir William, and he brought it out as his anchor. An entire Table of proportions was furnished; but that it might meet with no opposition from the influence of dockyard authority, it was sent to the officers of Portsmouth Yard for their approval. They returned it, after a few months, with some slight alterations in the proportions of some of the sizes, and recommended the construction to be on "Perring's principle" of the cushioned, or made-up, crown. It was so adopted, and continued to be made by Brown and Lenox for about a year or two, when the great and unnecessary expense incurred by the plan was pointed out. It was contended it was without any good; because, if the crown of the anchor, or any shut or weld, was made sound and perfect, the amalgamation of the grain of the iron would be complete, and assume its full power or strength, whatever way it might be put together; and the strongest form was that which exposed the least surface of iron to the welding heat, and consequently to injury. About the latter end of 1839, the subject was again opened. Mr. Lenox renewed his objections, by letter to Sir William Parker, to "Perring's plan" of shutting-up, and the consequence was — a contract, with specification, &c. &c., appeared, and an improved or modified plan of shutting-up (as it is called) was proposed by Mr. Tyler, master-smith of Portsmouth Yard, which was adopted; and Mr. Lenox's shape and proportions (slightly altered, as before said) came out as "Sir William Parker's," or the "Admiralty Anchor," and continued, until after the trials in 1852, with *every success in actual service that a good anchor could maintain*, and they were made and sold in quantities to all the world.



59



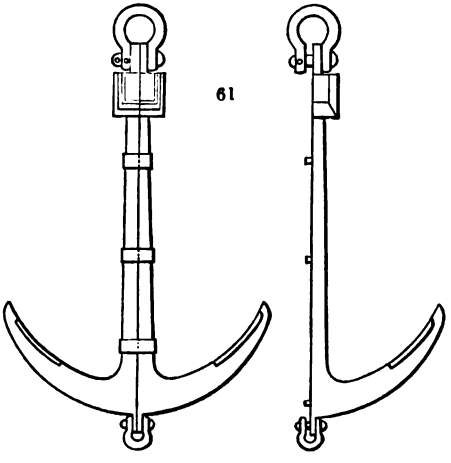
60

In the navy of England, and in nearly all foreign navies, this anchor, of which *fig.* 59 represents the form, was adopted. They are also largely employed in the mer-

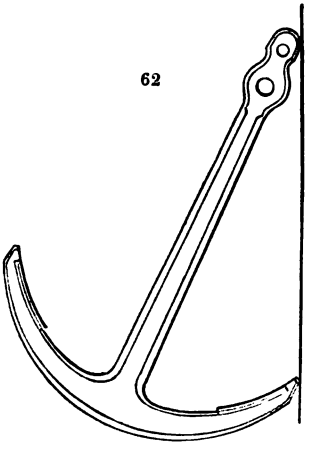
Digitized by Google

chant service; but these are not so nicely proportioned as the anchors made for the Government, nor are they so highly finished. Many merchant captains, however, take Rodger's anchor, and our steamers almost invariably take Porter's or Trotman's anchor.

Trotman's Anchor is represented in *fig.* 60, under its various positions. Although for convenience Trotman's anchor is, as we have already stated, largely used by the merchant steamers, we cannot but feel that the separation of the fluke from the shaft, although it may be in many cases unobjectionable, is attended with the risk that when, in an emergency, the anchor is required, the means of connexion may be at fault.

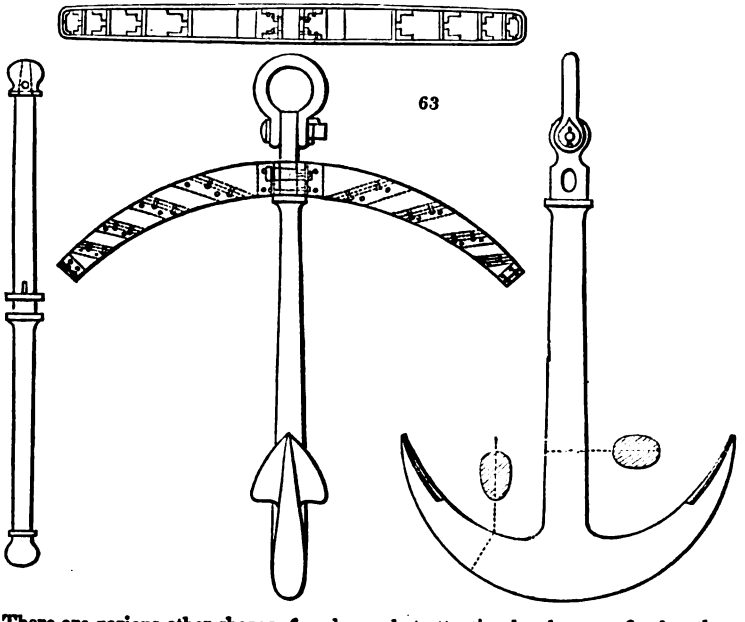


61



62

Captain Hall's anchor is a very valuable one, from the circumstance that it is capable of division, as shown in *fig.* 61, so that it can be taken out in boats.



63

There are various other shapes of anchors; but attention has been confined to those generally employed.

We are not in a position to offer any opinion upon the value of the several anchors

Digitized by Google

which have been named. Having described their peculiarities, there remains but little to be said. The solidity of Lenox's anchors—as shown in *fig.* 62, and again in their more recent modifications, in plan and section, with the new form of iron stock, *fig.* 63—has recommended them strongly, and hence their general use.

The weight of anchors for different vessels is proportioned to the tonnage. The following Tables show the number of Anchors now carried, and the weights of each anchor, by the ships of the Navy under the Admiralty regulations, and by merchant vessels by the regulation of Lloyd's.

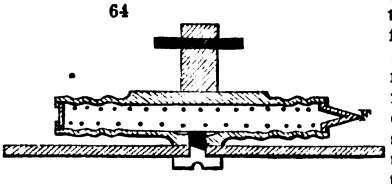
ANCHOVY. (*Anchois*, Fr.; *Acciughe*, It.; *Anschove*, Germ.) The *Clupea encrasicolus* of Linnæus (*Engraulis encrasicolus*), a small fish, common in the Mediterranean Sea. They are preserved as a delicacy, and used in the manufacture of anchovy sauce. The Gorgona anchovy is considered the best. They are abundant off the coasts of Cornwall and Wales, but the fishery is entirely neglected. See SARDINES.

ANDIRONS, or HAND-IRONS, also called Firedogs. Before the introduction of raised and close fireplaces these articles were in general use. Strutt, in 1775, says, "These *awndirons* are used at this day, and are called '*cob-irons*'; they stand on the hearth, where they burn wood, to lay it upon; their fronts are usually carved, with a round knob at the top; some of them are kept polished and bright: anciently many of them were embellished with a variety of ornaments."

ANEMOMETER (ἄνεμος, wind; μετρέω, to measure). An instrument or machine to measure the wind, its *direction* and *force*. Three descriptions of anemometers are now usually employed — 1, Dr. Whewell's; 2, Mr. Follett Osler's; 3, Dr. Robinson's. This is not the place to describe either of those most ingenious instruments, a full account of which will be found in the "Transactions of the British Association" and of the "Royal Irish Academy."

ANEROID BAROMETER. This instrument was invented by M. Vidi, of Paris. In its latest form it consists of a cylindrical case, about 4 or 6 inches in diameter, and 2¼ inches deep, in which lies a thin metal box, near to, and parallel with, the curved boundary of the case, its two ends being distant about half an inch from each other. From this box the air has been partially exhausted, and the pressure of the external atmosphere on it causes it to alter its form. The accompanying figure (64) shows a section of this box. It is made of thin corrugated plates of metal, so that its elasticity is great. By means of the tube F, the air is partially exhausted, when the box takes the form shown by the dotted lines. A small quantity of gas is introduced after exhaustion, the object of which is to compensate for the varying elasticity of the metal at different temperatures. The pressure of the air on the box in ordinary instruments is between 40 and 50 lbs., and it will be easily understood that any variation in this pressure will occasion the distances between the two plates to vary, and consequently the stalk will have a free motion in or out. This is, by an ingenious contrivance, changed from a vertical motion to a motion parallel to the face of the dial, and this is converted into a rotatory one by the application of a watch-chain to a small cylinder or drum. The original very slight

64



Digitized by Google

motion is augmented by the aid of levers. This is so effectually done, that when the corrugated surfaces move through only the 250th part of an inch, the index hand on the face turns over a space of three inches. The extreme portability of this little instrument, and its comparative freedom from risk of injury, renders it exceedingly useful to the traveller. Its accuracy is proved by the experiments of Professor Lloyd, who placed one under the receiver of an air-pump, and found that its indications corresponded with those of the mercurial guage to less than 0·01 of an inch; and within ordinary variations of atmospheric pressure the coincidences are very remarkable.—*Lloyd, Nichol, Drew.*

ANGELICA. (*Angélique*, Fr.; *Angelika*, Germ.) The *archangelica officinalis*. The dried angelica root is imported from Hamburg in casks. The tender stems, stalks, and the midribs of the leaves, are made, with sugar, into a sweetmeat (candied angelica). The angelica root and seeds are used by rectifiers and compounders in the preparation of gin, and as an aromatic flavouring for "bitters." The quantity cultivated in some moist places in this country is sufficient to meet our requirements.

ANGLE IRON. A piece of iron rolled out in the shape of ∠ to form joints.

ANGLESITE. A sulphate of lead found native, generally produced by the decomposition of galena (*sulphurate of lead*). It was first found at Pary's mine in Anglesea.

ANGORA WOOL. (*Poil de chevron d'Angora*, Fr.) Called also *angola* and *angona*. The wool of the Angora goat (*Capra Angorensis*), employed in the manufacture of shawls, camlets, and fine cloth, &c., is obtained from the long-haired goat of Angora, to which province this animal is peculiar. Lieutenant Conolly has given an account of this goat and some other varieties, *Capra lanigera*, the Cashmere goat, and *Changra* or the shawl-goat of Thibet:—

"The country where it is found was thus described to us—'Take Angora as a centre, then Kizzil Ermak (or Haly's) Chomgere, and from eight to ten hours' march (say thirty miles) beyond; Beybazar, and the same distance beyond, to near Nalaban; Sevree, Hissar, Yoorrook, Tosiah, Costambool, Geredeh, and Cherkesh, from the whole of which tract the common bristly goat is excluded, and the white-haired goat alone is found.' The fleece of the white Angora goat is called *tiftik* (the Turkish for goat's hair), in distinction to *yun*, or *yapak*, sheep's wool. After the goats have completed their first year, they are clipped annually, in April or May, and yield progressively, until they attain full growth, from 150 drachms to 1½ *oke* of *tiftik* (from 1 lb. to 4 lbs. English)." The hair of the tiftik goat is exported from its native districts raw, in yarn, and woven in the delicate stuffs for which Angora has been long celebrated. The last are chiefly consumed in Turkey, while the yarn and raw material are sent to France and England. It appears that the first parcels of Angora wool were shipped from Constantinople for England in 1820, and was so little appreciated that it fetched only 10*d.* the pound.

"Within the last two or three years, a new texture made of goats' wool has, however, been introduced both into France and this country, which calls for particular attention. This texture consists of stripes and checks expressly manufactured for ladies' dresses, and having a soft feel and silky appearance. The wool of which this article is made is chiefly the wool of the Angora goat. This wool reaches us through the Mediterranean, and is chiefly shipped at Smyrna and Constantinople. In colour it is the whitest known in the trade, and now more generally used in the manufacture of fine goods than any other. There are, however, other parts of Asiatic Turkey from which limited supplies are received; but in quality not so good as that produced in Angora. After the manufacture of shawls with goats' wool declined in France, this raw material remained neglected for a long while. About two or three years ago (1852), however, the French made another attempt, and brought out a texture for ladies' dresses in checks and stripes, which they call '*poil de chevre*.' The warp is a fine spun silk, coloured, and the weft Angora or Syrian white wool, which was thus thrown on the surface. This article has a soft feel, and looks pretty, but in wearing is apt to cut. The price of a dress of French manufacture has been from 2*l.* 10*s.* to 3*l.*; but by adopting a cotton warp, the same article is now made in England and sold for 15*s.*; and it is found that the cotton warp, as a mixture, suits the goats' hair best."—*Southey on Colonial Sheep and Wools*, London, 1852.

The principal manufactures of "*poil de chevre*" in France are at Paris, Cronyen, Thelle (Oise), Ecrus (Oise), Montataire (Oise), and Ledau. In England, the wool is chiefly spun at Bradford, and partly manufactured there; at Norwich, and also in Scotland; part of the yarn is exported. Mr. Southey informs us, that the quantity of goats' wool imported into the United Kingdom in 1848, was 896,865 lbs.; in 1849 the quantity rose to 2,536,039 lbs. The following returns show the progress of this industry. The total importation of goat's hair and wool was as follows:—

	1846.	1847.	1848.	1849.	1850.
Goat's wool, bales -	5,231	7,023	5,468	13,254	12,884

Digitized by Google

In 1850 we imported from Turkey 2,574,724 lbs., the computed real value of which was 278,928*l.* In 1863 our total importation of goat's hair and wool was 3,434,705lbs., which at the average price fixed for the value, 2*s.* 10⅝*d.* per lb., gave the computed real value as 502,728*l.* Of this quantity we imported 2,128,633 lbs. from Turkey, and 899,972 lbs. from France. Angora goat's wool is used for the manufacture of plush, and for coach and decorative laces. It is also used extensively for buttons, and is made up into a light cloth, for paletôts and overcoats.

In France this article is now applied to the manufacture of a new kind of lace, which in a great measure supersedes the costly fabrics of Valenciennes and Chantilly. The Angora-wool lace is more brilliant than that made from silk, and costing only half the price, it has come into very general wear among the middle classes. The same material is also manufactured into shawls, which sell from 4*l.* to 16*l.* each. See MOHAIR and CASHMERE.

ANHYDRIDES. A name now given by chemists to the oxygen-acids, or those acids which are clearly results of a combination of an element with oxygen as sulphurous acid.

ANIL. The name of the American species of the Indigo plant (*Indigofera*). It is a shrubby plant, growing from 2½ to 3 feet high. From it the name *Aniline* is derived. See ANILINE and INDIGO.

ANILEINE. See ANILINE VIOLET.

ANILINE. ($C^{12}H^7N$, or *Unitary System*, $C^6H^5, H, H=N$). This organic base having recently met with an important application in the arts, in the production of beautiful dye-colours, a description of the methods of preparing it, and of some of its characters, becomes necessary; though for details of its more interesting relations in scientific chemistry, we must refer to Watts' "Dictionary of Chemistry."

Preparation.—There are few bodies which admit of being prepared in a greater variety of ways—all of them interesting in tracing the chemical history of this most curious body; but we will only here describe that one which might be most advantageously carried out on a manufacturing scale. Probably the most abundant source of aniline is the basic oil of coal tar.

The oil is agitated with hydrochloric acid, which seizes upon the basic oils; after decanting the clear liquor, which contains the hydrochlorates of these oils, it is evaporated over an open fire until it begins to disengage acrid fumes, which indicate a commencement of decomposition, and then filtered, to separate any adhering neutral compounds. The clear liquor is then decomposed with potash or milk of lime, which liberates the bases themselves in the form of a brown oil, consisting chiefly of a mixture of aniline ($C^{12}H^7N$), and leucol or quinoleine ($C^{18}H^9N$). This mixture is submitted to distillation, and the aniline is chiefly found in that portion which passes over at or about 360° F. (182° C.): repeated rectification and collection of the product distilling at this temperature purifies the aniline; but to complete the purification, it is well to treat the partially purified aniline once more with hydrochloric acid, to separate the bases again by an alkali, and then to rectify carefully.

The violet reaction of aniline with solution of bleaching powder enables the operator to test the distillate from time to time, to ascertain when aniline ceases to pass over, since leucol does not possess this property.—*Hofmann.*

Aniline may also be obtained in quantity from indigo.

When indigo-blue (see INDIGO) is dissolved by the aid of heat in a strong solution of potash, and the mass, after evaporation to dryness, submitted to destructive distillation, it intumesces considerably, and aniline is liberated, which condenses in the receiver in the form of a brown oil, together with a little water and ammonia disengaged with it. The aniline is purified by rectification, as in the method before described. By this process, the quantity of aniline obtained is about 18 to 20 per cent. of the indigo used.—*Fritzche.*

By treatment with potash, the indigo-blue ($C^{16}H^5NO^2$) is converted into chrysanilic acid and anthranilic acid ($C^{14}H^7NO^4$), and it is this latter body which, by destructive distillation, yields carbonic acid and aniline.

$$C^{14}H^7NO^4 = C^{12}H^7N + 2CO^2.$$

Nitrobenzole (*which see*) may be converted into aniline, either by the action of sulphuretted hydrogen—

$$\underbrace{C^{12}H^5NO^4}_{\text{Nitrobenzol.}} + 6HS = \underbrace{C^{12}H^7N}_{\text{Aniline.}} + 4HO + 6S,$$

or, more conveniently, as has been recently shown by M. Béchamp, by the action of a basic acetate of iron.

For this purpose, the following proportions have been found convenient by the writer: mix in a retort ½ lb. of iron filings, with about 2 ounces of acetic acid, then add about an equal volume of nitrobenzole. After a few minutes a brisk effervescence

Digitized by Google

sets in, and the aniline distils over together with water. The reaction may require to be aided by the application of a very gentle heat; but it takes place with the greatest ease, and a very tolerably sufficient condensing arrangement should be employed. The aniline having so nearly the density of water, does not readily separate on the surface, but the addition of a few drops of ether, which dissolves in the aniline, brings it to the surface. It may then be decanted off, dried by standing for a short time over chloride of calcium, and then purified by rectification, as before described.

Properties.—Aniline is one of the organic basic derivatives of ammonia. In fact, it may be be viewed as ammonia in which one equivalent of hydrogen is replaced by the compound radical *Phenyl* ($C^{12}H^5$), thus :—

$$N\left\{\begin{matrix} C^{12}H^5 \\ H \\ H \end{matrix}\right.$$

Just as phenyl is one of a series of homologous radicals, so aniline is the first of a series of homologous bases, in which the one equivalent of hydrogen is replaced by these radicals respectively, thus :

Homologous Radicals.		Homologous Bases.
Phenyl - - -	$C^{12}H^5$ —	Aniline - - - $N\left\{\begin{matrix} C^{12}H^5 \\ H^2 \end{matrix}\right.$
Toluyl - - -	$C^{14}H^7$ —	Toluidine - - - $N\left\{\begin{matrix} C^{14}H^7 \\ H^2 \end{matrix}\right.$
Xylyl - - -	$C^{16}H^9$ —	Xylidine - - - $N\left\{\begin{matrix} C^{16}H^9 \\ H^2 \end{matrix}\right.$
Cumyl - - -	$C^{18}H^{11}$ —	Cumidine - - - $N\left\{\begin{matrix} C^{18}H^{11} \\ H^2 \end{matrix}\right.$
Cymyl - - -	$C^{20}H^{13}$ —	Cymidine - - - $N\left\{\begin{matrix} C^{20}H^{13} \\ H^2 \end{matrix}\right.$

When pure, it is a colourless liquid of a high refractive power, density 1·028, and of an aromatic odour. It is slightly soluble in water, and mixes in all proportions with alcohol and ether. It boils at 360° F. (182° C.) It dissolves sulphur and phosphorus when cold and coagulates albumen. It has no action on litmus-paper, but turns delicate vegetable colours, such as dahlia-petal infusion, blue.

Its basic characters are well developed thus :—it precipitates the oxides from the salts of iron, zinc, and alumina, just like ammonia, and yields, with bichloride of platinum, a double salt similar to ammonia, the platino-chloride of aniline ($C^{12}H^7N$,HCl,$PtCl^2$), which on ignition is entirely decomposed, leaving only a residue of platinum. These characters, together with the beautiful blue colour which it strikes with solution of bleaching powder, or the alkaline hypochlorites generally, are sufficient for the recognition and distinction of this body.

Salts of Aniline.—Aniline combines with acids forming a long series of salts which are in every respect analogous to the corresponding salts of ammonia. They are nearly all soluble and crystallisable, and are decomposed by the mineral alkalis with liberation of aniline. They are generally colourless, but become red by exposure to the air.

Sulphate of Aniline. ($C^{12}H^7N$; HO, SO^3)—This salt is employed in the manufacture of Mr. Perkin's aniline colours. It is prepared by treating aniline with dilute sulphuric acid, and evaporating gently till the salt separates. It crystallises from boiling alcohol in the form of beautiful colourless plates of a silvery lustre, for the salt is scarcely at all soluble in cold alcohol. It is very soluble in water, but insoluble in ether.

The crystals redden by exposure to the air; they can be heated to the boiling point of water without change, but when ignited they are charred with disengagement of aniline and sulphurous acid.

Oxalate of Aniline. ($C^{12}H^7N$; HO, C^2O^3)—This is one of the best defined salts of aniline: it separates as a crystalline mass on treating an alcoholic solution of oxalic acid with aniline. It is very soluble in hot water, much less so in cold, only slightly soluble in alcohol, and insoluble in ether.

A large number of other salts are known. The hydrochlorate, hydrobromate, hydriodate, nitrate, several phosphates, citrate, tartrate, &c. &c.; but they are of purely scientific interest. The same remark applies to the various products of the decomposition of aniline, which have been so ably investigated by Fritzche, Zinin, Hofmann, Gerhardt, and other chemists.

Since this was written, the Aniline dyes have received such an important development, that it is necessary to give a more detailed description of these beautiful colours.

Digitized by Google

It appears desirable that a Dictionary of the Arts should comprehend a succinct history of the discovery of a body which has performed so important a part in the advancement of a special industry as Aniline has done.

In 1826 Unverdorben, a German chemist, when exposing indigo to destructive distillation, discovered an oily substance which formed crystalline compounds with acids, to which he gave the name of *Crystalline*. Runge, also a German, subsequently observed in coal-tar oil a substance capable of forming saline compounds, and of striking a violet-blue colour with chloride of lime. To this he gave the name of *Kyanol*, blue oil. At a later period Fritzsche, when investigating the action of potash on indigo, obtained a quantity of a basic oil, which he analysed, and to which he gave the name of *Aniline*. Zinin, about the same time, found that *Nitrobenzol* (see this article), when submitted to the action of sulphuretted hydrogen, was converted into a peculiar and, as he thought, a new substance, to which he gave the name of *Benzidam* (an ammonia derived from Benzol). Hofmann was the first who submitted crystalline, kyanol, aniline, and benzidam to careful experimental comparison, and proved them to be identically the same substance, which now took its place in chemistry under the name of aniline.

In 1825 Michael Faraday, during an examination of the oily products separated in the compressed oil-gas holders—then largely used—discovered *Benzol*, which he then described as a bicarburetted hydrogen. On this important discovery, Dr. Hofmann remarks: "In this investigation, as indeed throughout the whole series of his immortal researches, Faraday's object was the elaboration of truth for its own intrinsic value and beauty; and in the same spirit has the work been continued by those who, after Faraday, engaged in the further scientific examination of this subject. Nobody in those early days of benzol, when the substance simply existed as a laboratory curiosity, dreamed of the brilliant career looming in the distance for this body, nor of the marvellous transformation it was destined to undergo. But the experience of the last few years in this matter has only corroborated the old axiom, which cannot be too often repeated, that the search after the true, for its own sake, leads on to the discovery of its natural corollaries, the useful and the beautiful. For those, indeed, lie folded up in truth, to be in due time evolved therefrom, even as the great tree unfolds itself from out the little seed."

Mitscherlich, some years later, found the benzoic acid, distilled with caustic potash, gave a colourless volatile liquid, indentical with the hydrocarbon discovered by Faraday; and hence the name this substance now retains—Benzol. Dr. Hofmann, in 1845, proved the presence of benzol in coal-tar oil, and in 1848 Mansfield showed that an inexhaustible quantity of it could be procured from that source. See BENZOL.

Now, the crude tar of the gasworks is subjected to regulated distillation. Thus is obtained separately *naphtha* or *light oil* (oily liquid lighter than water), and then *dead oil* or *heavy oil* (oily liquid heavier than water), and finally remaining in the retort pitch. From the light oil, benzol is separated by further fractional distillation. Mitscherlich showed, if this benzol is dissolved in fuming nitric acid, and the clear liquid mixed with water, a compound (nitrobenzol) is precipitated as a dense yellow liquid. This is the well-known artificial oil of bitter almonds, which is now prepared easily and economically on a large scale. See NITROBENZOL. It was Zinin, already named, who discovered that sulphuretted hydrogen converted this nitrobenzol into aniline, and who, believing the substance thus produced to be a new one, described it under the name of benzidam, or an ammonia derived from benzol.

The successive changes of benzol are thus expressed in chemical symbols. (*Hofmann*):—*Unitary System.*

First change.

Transformation of benzol into nitrobenzol.

$$\underbrace{C_6H_6}_{\text{Benzol.}} + \underbrace{HNO_3}_{\text{Nitric Acid.}} = \underbrace{C_6H_5NO_2}_{\text{Nitrobenzol.}} + \underbrace{H_2O}_{\text{Water.}}$$

Second Change.

Transformation of nitrobenzol into aniline.

$$\underbrace{C_6H_5NO_2}_{\text{Nitro-benzol.}} + \underbrace{3H_2S}_{\text{Sulphuretted Hydrogen.}} = \underbrace{C_6H_7N}_{\text{Aniline.}} + \underbrace{2H_2O}_{\text{Water.}} + \underbrace{3S}_{\text{Sulphur.}}$$

Dr. Hofmann remarks that sulphuretted hydrogen is not by any means the most convenient reducing agent to effect this conversion, and he has shown that when nitrobenzol is placed in contact with metallic zinc and hydrochloric acid, it is

Digitized by Google

rapidly converted into aniline. Béchamp submitted nitrobenzol to the action of metallic iron and acetic acid, and thus transformed it into aniline. This process is now almost universally adopted. Equal weights of nitrobenzol, acetic acid, and cast-iron turnings are very gradually mixed in cast-iron vessels, so that the heat produced by the reaction does not raise the temperature of the mixture too high. The semisolid mass which is produced consists of acetate of iron and acetate of aniline. This is distilled sometimes alone, or by some manufacturers with the addition of lime; the distillate consisting generally of acetone, aniline, unaltered nitrobenzol, and several other products arising from the impurity of the nitrobenzol. The crude aniline mixture is redistilled, and the aniline obtained sufficiently pure by collecting the products distilling between 175° C and 190° C. Thus produced, aniline is a slightly brownish liquid, a little heavier than water.

ANILINE, BLACK. This colour can scarcely be said to have been satisfactorily produced. The green tints (see ANILINE, GREEN) are turned black, according to a process devised by Messrs. Wood and Wright, by mixing chlorate of potassium with a metallic salt and a salt of aniline; for the metallic salt they prefer ferric salts. Aniline black may also be produced by treating the colour on the fabric by solutions of bichromate of potassium, or of weak bleaching powder. Nitrate of copper may be mixed with hydrochlorate of aniline, without the addition of chlorate of potassium, and the mixture printed on the fabric, when gradually a black tint is produced.

ANILINE, BLUE. MM. Girard and De Laire, in M. Pelouze's laboratory, discovered the reactions which give rise to the aniline blues. This reaction consists in heating a salt of rosaniline, or a mixture of substances capable of giving rise to its formation, for several hours with an excess of aniline. The blue colouring-matter thus obtained is the *Bleu de Paris* and the *Bleu de Lyon*. The operation on a large scale is carried out by allowing the mixture of a salt of rosaniline, with an excess of aniline, to digest at a temperature of 150° or 160° for a considerable time. If a mixture of 2 kilogrammes of dry hydrochlorate of rosaniline and 4 kilogrammes of aniline be employed, the operation is completed in four hours. The crude blue is purified, by treating it successively with boiling-water, acidulated with hydrochloric acid, and with pure water, until it presents the purest possible hue. Mr. Nicholson has devised and patented a process of purifying the blue colouring-matter, which he dissolves for this purpose in concentrated sulphuric acid, afterwards digesting the solution for half an hour at a temperature of 150° C. On adding water to this solution, the blue colouring-matter is precipitated in a modified condition, having, in fact, become soluble in pure water.

Dr. Hofmann has determined the nature of aniline blue, which he thus describes:—"The blue colouring-matters, as might have been expected, are saline compounds of a colourless base, which may be obtained in a state of perfect purity by dissolving one of the salts (the hydrochlorate, for instance) in alcohol, and filtering the solution into alcoholic ammonia. The deep-blue immediately disappears, and the slightly reddish solution yields the free base on addition of water, in the form of a white curdy precipitate, which gradually assumes an indistinctly crystalline character. Dried *in vacuo*, this substance remains colourless, or assumes a slightly bluish tint; at 100° it cakes, and becomes brown; and is found by analysis to contain—

$$C_{36}H_{33}N_3O = C_{36}H_{31}N_3,H_2O.$$

This formula exhibits an extremely simple relation between aniline blue and aniline red; indeed, aniline blue is triphenylic rosaniline:—

Aniline red $C_{20}\ H_{19}\ N_3,H_2O$ Rosaniline.

Aniline blue $C_{20}\left[\begin{matrix}H_{16}\\C_6H_5\end{matrix}\right]\ N_3,\ H_2\ O$ { Triphenylic Rosaniline.

The salts of the triphenylic derivative correspond to the rosaniline salts. The composition of the hydrochlorate, which Mr. Nicholson prepares in a state of perfect purity, is analogous to that of the monacid hydrochlorate of rosaniline:—

Hydrochlorate of rosaniline $C_{20}\ H_{19}\ N_3$, HGI.

Hydrochlorate of triphenylic rosaniline $C_{20}\left[\begin{matrix}H_{16}\\C_6H_5\end{matrix}\right]N_3$,HCl.

The genesis of aniline blue is represented by the following equation:—

$$\underbrace{G_{20}H_{19}N_3,\ HCl}_{\text{Hydrochlorate of Rosaniline.}} + 3\underbrace{\left[\begin{matrix}C_6H_5\\H_2\end{matrix}\right\}N\Big]}_{\text{Aniline.}} = C_{20}\underbrace{\left[\begin{matrix}H_{16}\\(C_6H_5)_3\end{matrix}\right]N_3,\ HCl}_{\text{Hydrochlorate of Triphenylic Rosaniline.}} + \underbrace{3H_3N.}_{\text{Ammonia.}}$$

Digitized by Google

Aniline blue, when submitted to the action of reducing agents, such as nascent hydrogen or sulphide of ammonium, is converted into a colourless difficultly crystallisable substance, which in composition corresponds to leucaniline. It contains $C_{32}H_{33}N_3$."

The recognition of the nature of aniline blue has led Dr. Hofmann to some experiments which seem likely to become of industrial importance. Seeing that the substitution of three atoms of phenyl for three atoms of hydrogen in rosaniline induces a change from red to blue, the idea naturally suggested itself to replace the hydrogen by other radicals, such as methyl, ethyl, and amyl. Experiment has furnished results of some interest. Rosaniline is readily attacked by the iodides of these radicals: a series of new substances being produced, obviously the salts of trimethyl, triethyl, and triamyl rosaniline, the blue colours of which are similar to that of the phenylated compound. These new colouring-matters are still under examination.

Under the title of "*Improvements in preparing colouring matters for Dyeing and Printing*," Dr. Hofmann patented (sealed August 29th 1863), the following processes. I take the substance now well known as "rosaniline," being the base obtained from the various salts of rosaniline found in commerce under the names of "roseine," "magenta," and also by other names, and which is usually prepared from aniline and the homologues thereof, and I mix it with the iodides, bromides, or other salts of the "alcohol radicals," such as iodide of ethyl, methyl, or amyl, or bromides of the same. I employ the substances, by preference, in the proportion of one equivalent of rosaniline to three equivalents of the salt of the alcohol radical; I then heat the mixture either alone or together with methylatic spirit to a temperature between 212° and 300° Fahrenheit in a close vessel under pressure; it is convenient to use an iron boiler provided with a safety valve. I continue the heat until the desired result is obtained. During the heating the mixture passes through several phases of coloration, being eventually converted into a blue substance. If the process is stopped before the whole is converted into the blue, the mixture is then of a violet or purple colour. For the purpose of dyeing and printing the mixture may be used in the same manner as that in which the aniline colours are employed.

ANILINE, GREEN. Aniline assumes a beautiful indigo-blue colour by the action of chlorate of potassium, to which a quantity of hydrochloric acid has been added, and also under the influence of a solution of chlorous acid. Dr. Crace Calvert and Messrs. Lowe and Clift have produced similar blues, and described them under the name of *Azurine*. Most of these blues possess the property of acquiring, under the influence of acids, a green tint called *Emeraldine*. Dr. Calvert obtains this colour directly upon cloth by printing with a mixture of an aniline salt and chlorate of potassium, and allowing it to dry. In about twelve hours the green colour is developed. This colour may be converted into blue by being passed through a hot dilute alkaline solution, or through a bath of boiling soap. See VERDINE.

ANILINE, RED. The discovery of this colour is clearly due to Dr. Hofmann. In 1858 this able chemist wrote, in the "Proceedings of the Royal Society" (vol. ix. p. 284) as follows:—"The aqueous solution yields, on addition of potassa, an oily precipitate containing a considerable portion of unchanged aniline; on boiling this precipitate with dilute potassa in a retort, the aniline distils over, whilst a viscid oil remains behind, which generally solidifies with a crystalline structure. Washing with cold alcohol, and two or three crystallisations from boiling alcohol, render this body perfectly white and pure, *a very soluble substance of a magnificent crimson colour* remaining in solution. The portion of the black mass, which is insoluble in water, dissolves almost entirely in dilute hydrochloric acid, from which it is reprecipitated by the alkalis in the form of an amorphous pink or dingy precipitate soluble in alcohol, with a *rich crimson colour*. The greater portion of this body consists of the same colouring principle, which accompanies the white crystalline substance."

This red coloration was indeed noticed in 1843 by Dr. Hofmann, while studying the action of fuming nitric acid upon aniline. In 1856 Natanson observed it when examining the action of Dutch liquid upon aniline. The industrial discovery of aniline red was made in 1859 by Messrs. Verguin and Renard Brothers, of Lyons. Their process for obtaining it was as follows:—A mixture of ten parts of aniline, and from six to seven parts of tetrachloride of tin, either anhydrous or hydrated, is heated to ebullition for fifteen or twenty minutes. The liquid first becomes yellow, and then gradually more and more red, until at last the colour is so intense that the mass appears black. The mixture is allowed to cool, and then treated with a large quantity of boiling-water, which acquires a magnificent red colour, and, without any other preparation, forms a splendid dye both for silk and wool. It is found advisable to previously purify the red colouring-matter, for which purpose its insolubility in saline solutions is made available. If the concentrated red liquid be partially saturated with carbonate of sodium, and a quantity of common salt added, the aniline

Digitized by Google

red is precipitated in a solid state, and constitutes the *fuchsine* of the chemist. This has only to be dissolved in water, alcohol, or acetic acid to prepare the dye-bath.

Renard and Frane stated, at the same time, that anhydrous, mercuric, ferric, and cupric chlorides might be used in the place of the chloride of tin.

Several other processes for obtaining aniline red were suggested, and some of them used. Gerber-Keller treated aniline with the nitrates of mercury. Lauth and Depouilly used nitric acid; and six months before the discovery by these French dyers, two English chemists—Medlock and Nicholson—had separately patented, within a few days of each other, as the result of their experiments, a similar process.

Medlock and Nicholson, and Girard and De Laire all, in 1860, patented the use of arsenic acid. This process, being now almost exclusively employed, must be described. Arsenic acid is combined with a slight excess of aniline; the crystalline mass is heated by means of a slow fire to about 120° to 140° C., care being taken not to exceed 160° C. The operation, according to the scale on which it is carried on, requires from four to nine hours for completion. A perfectly homogeneous mass, fluid above 100° C., is thus obtained, which on cooling solidifies to a hard substance, with metallic bronze-coloured lustre. When dissolved in boiling water it produces a solution of great richness and purity of colour. If, in the treatment of aniline with arsenic acid, the latter be considerably beyond the proportion of aniline employed, *violet* and *blue dyes* may be formed. The production of such has been patented by Girard and De Laire.

Laurent and Casthélaz have obtained aniline red direct from benzol, without the preliminary isolation of aniline. Nitrobenzol is treated with a mixture of iron and hydrochloric acid, or with ferric chloride. On heating the mixture, the ferric chloride reacts on the aniline contained in the mixture, transforming it into aniline red. It is doubtful if the colouring-matter obtained by this process is equal in beauty to that procured from the aniline. The name of *erythrobenzol* was given by the discoverers to the colouring-matter thus obtained, but it probably consists principally of rosaniline. "The method is ingenious, and, if the product be equal in point of quantity and quality to that obtained by means of the previously prepared aniline (a doubtful question, to say the least), it must be an economical plan, since it disposes entirely with one rather delicate operation, and thus diminishes the amount of manual labour required."—*Hofmann.*

The processes described are amongst the best yet devised for the preparation of crude aniline red. Numerous other methods have been patented, amongst others the following:—

Messrs. Renard Brothers include in their patent the ebullition of aniline with stannous, stannic, mercurious, and mercuric sulphates, with ferric and uranic nitrates and nitrate of silver, and with stannic and mercuric bromides.

Messrs. John Dale and Caro patent the action of nitrate of lead upon aniline, or hydrochlorate of aniline.

Mr. Smith claims the ebullition of aniline with perchloride of antimony, or the action of antimonic acid, peroxide of bismuth, stannic, ferric, mercuric, and cupric oxides upon hydrochlorate or sulphate of aniline at the temperature of 180°.

M. Gerber-Keller (Heilmann in England) claims the production of aniline red from all the metallic salts of the oxides of nitrogen—sulphur, chlorine, bromine, iodine, phosphorus, arsenic, and, in fact, almost every compound within the range of chemistry. It may well be said of such patents, that "scientific men cannot speak otherwise than in terms of reprehension. Their claims are founded on random guesswork, not on the results of patient investigation. They are attempts to pre-occupy the whole field, and forestall all the rewards which should be left open to real inventive genius to cultivate and win."—*Hofmann.*

These processes have reference to the preparation of crude aniline red. The crude colours contain some undecomposed aniline, mostly in the form of salts. They contain also tarry matters, some insoluble in water and dilute acids; others soluble in bisulphide of carbon, naphtha, or in caustic or carbonated alkalis. If, therefore, the crude red be boiled with an excess of alkali, the undecomposed aniline is expelled, the acid which exists in the product being fixed. On treating the residue with acidulated boiling-water, the red is dissolved, while certain tarry matters remain insoluble. If now the boiling solution be filtered, and then saturated with an alkali, the colouring-matter is precipitated in a tolerable state of purity. By redissolving the precipitated red in an acid, not employed in excess, a solution is obtained which frequently crystallises, or from which a pure red may be thrown down by a new addition of chloride of sodium, or other alkaline salt. The hydrochlorate of aniline red is employed in dyeing in France, while the acetate is used in England.

To Dr. Hofmann we are principally indebted for the investigation into the nature of aniline red. In his paper on the "Formation of Aniline Red," he says, he is

Digitized by Google

"painfully aware of the imperfections of his researches upon this subject: as yet only a corner of the veil which conceals the truth is raised. The genesis and constitution of aniline red still remain to be investigated, though the chemical nature and composition of the substance itself are no longer doubtful."

Aniline reds are salts of a very remarkable compound, which plays the part of a well-defined base, and to which Dr. Hofmann gave the name of *rosaniline*. (See ROSANILINE.) This compound, in its anhydrous state, is represented by the formula of C_{20} H_{19} N_3 (*Unitary System*). The formation of aniline red will be best given in Dr. Hofmann's own words:—

"It had been observed by many manufacturers that some varieties of commercial aniline yield much more rosaniline than others. Samples of aniline, boiling at temperatures much higher than the boiling-point of the pure compound, are found to be particularly adapted for the production of the red. This observation led Dr. Hofmann to examine carefully the deportment of *pure* aniline under the influence of the several agents by which *commercial* aniline is converted into aniline red. To this examination he subjected a sample of pure aniline derived from indigo, and other samples made from pure benzol; this being derived in some cases from benzoic acid, in other cases from coal-tar. These experiments elicited the remarkable fact, *that pure aniline, from whatever source obtained, is incapable of furnishing the red dye*—a result fully confirmed by Mr. E. C. Nicholson, who indeed had been long acquainted with this circumstance. It thus became obvious that commercial aniline must contain another base, the presence of which determines the formation of the colouring-matter. The idea very naturally suggested itself that *toluidine*—which, owing to the difficulty of separating toluol from benzol, is always present in commercial aniline—might be the true source of the colouring-matter. Experiments made with *pure* toluidine showed, however, that this base is not more capable of yielding the red than pure aniline itself. But *the red colouring-matter is instantaneously produced when a mixture of pure aniline and pure toluidine is treated with the chlorides of mercury or tin, or with arsenic acid*, plainly showing that the two bases must co-operate in the formation of the red.

This result, Dr. Hofmann believes, contains the clue by which may be explained not only the genesis of aniline red, but also that of the tinctorial ammonias generally. It points, moreover, to the necessity of ascertaining how far the formation of the violet and other colouring-matters, hitherto believed to be exclusively derived from aniline, require the co-operation of toluidine. Dr. Hofmann has experiments in hand on this and some collateral points.

Returning to the red derivatives of aniline obtained by the different processes above described, we may state broadly that all these products are composed essentially of rosaniline salts. The red, prepared by the process of Messrs. Renard and Frane, or Fuchsine, consists chiefly of hydrochlorate of rosaniline. The azalëine, or aniline red prepared by nitric acid, is principally nitrate of rosaniline.

In the crude red, produced by the action of arsenic acid, we should find the arseniate of rosaniline, which by the subsequent treatment, for the sake of purification, is converted into hydrochlorate or acetate of rosaniline.

This is the place to record the fact that for some time past a colourless (or at least slightly rose-coloured) paste, with an alkaline reaction, has been delivered into commerce from Malhouse, in France; which paste has only to be treated with acetic acid, in which it dissolves with the greatest facility, in order to obtain an extremely rich and beautiful carmine solution, capable of being at once employed for printing stuffs. Now that the characters of rosaniline are known, there cannot be the least doubt that this colourless paste consists almost entirely of rosaniline more or less pure, and that it has been prepared by precipitating a solution of a rosaniline salt (nitrate) by an excess of a powerful base, such as soda or lime.

Remarks on the Phenomena observed in the Applications of Aniline Red.—We are now, moreover, enabled to explain perfectly what takes place when a stuff which has been dyed with aniline red is acted upon by a powerful acid or alkali. On printing with a powerful acid the stuff is decolorised with the formation of a yellowish stain, because a rosaniline salt with the equivalents of acid is formed; the triacid salts of this substance being in fact all yellowish, and possessing but little colour. When the material is washed with water, the excess of acid is removed, and the monoacid salt reproduced, the red colour being restored.

On printing with a powerful base, for example, with caustic soda, the red disappears as the red rosaniline salt is decomposed, and rosaniline liberated in a colourless condition. But on washing out the soda with water, the red colour reappears, the rosaniline becoming probably carbonated.

If a powerful volatile base be employed as ammonia, the red also disappears, on account of the liberation of the colourless rosaniline; but in proportion as the ammonia evaporates the red coloration returns, particularly on slightly warming—as

Digitized by Google

the rosaniline, which is a fixed base, expels the ammonia, and re-forms the primitive salt of rosaniline with its peculiar colour. If the rosaniline-dyed fabric be left for a considerable length of time (from twelve to twenty hours) in contact with weak ammonia, the colour, as has been pointed out by Mr. W. Crum, scarcely returns on rinsing with water. This is obviously due to the increased solubility of rosaniline in water containing ammonia, which separates the colouring-matter even from the mordant.

The salts of rosaniline, which are chiefly employed for dyeing silk and wool, are the acetate, the hydrochlorate, and the nitrate, and their application is simple in the extreme. The silk is dyed by passing it through a cold aqueous solution of the salt: for the dyeing of wool the solution is heated to a temperature varying between 50° and 60° C.

The force and rapidity with which rosaniline is fixed by silk and wool is the only difficulty to be encountered in this branch of dyeing. In fact, this magnificent colour is precipitated and fixed with such avidity and promptitude by silk and wool, that it is necessary to take particular precautions, and to operate with solutions that are at first comparatively weak, and are only gradually strengthened, to prevent the dyeing being unequal, and the portions first immersed in the bath being more strongly coloured than those afterwards introduced. Cotton is also difficult to dye with rosaniline salts, but for the exactly opposite reason—that it does not present any attraction for this colouring-matter. The fixation of the colour on cotton can, therefore only be effected by first treating the cotton with some animal mordant, or with tannic acid.

There are two modes of proceeding for this purpose:—

1. The fabric is printed with the thickened organic mordant; for goods intended to be dyed throughout the mordant is uniformly spread on the whole surface of the stuff, and fixed either by drying or steaming before the fabrics are introduced into the dye-bath. The colour is only fixed on the mordanted portions, and the shades themselves may be varied according to the nature and composition of the mordant.

Among the substances employed as organic mordants for rosaniline are:—Albumin, whether made from white of egg or from blood; prepared glutin, prepared casein or actarin, gelatin, and tannin—this latter being used either in its combinations with the metallic oxides (as antimonic, stannic, or plumbic), or as tannate of gelatin. For some time oily preparations were employed, as, for example, the sulphomargaric and sulpholeic acids.

2. The mordant is thickened, and at the same time some aniline red is dissolved in it; the stuff is printed therewith, dried, and steamed; the whole is then fixed on the fabric, which then has only to be washed and dried.

This method is principally employed when using albumin, in which acetate of rosaniline is dissolved. Latterly tannin has been employed in preference for fixing aniline red, particularly in dyeing ordinary articles; for the mordanting of which albumin, although giving the most satisfactory results, is too costly an article.

It is to Mr. Perkin that we are indebted for the first application of tannin for fixing aniline colours upon cotton.

MM. Kuhlemann and Lightfoot have called attention to the advantages presented by the use of tannate of gelatin; and Mr. Walter Crum has minutely indicated the treatment by which glutin, the cheapest substitute for albumin, may be rendered available in printing and dyeing with aniline colours.

ANILINE VIOLET. To this colour in its varieties the names of *Mauve*, *Anileine*, *Indisine*, *Phenameine*, *Violine*, *Rosolane*, *Tyroline*, &c. have been given. Mr. Perkins' patent dates from 26th August 1856, and this was the original of all the numerous colorific compounds commercially produced. Aniline violet was first obtained in the crystalline condition in 1860 by M. Scheurer-Kestner, who used monohydrated acetic acid as a solvent. Dr. Hofmann informs us that in 1862 Kestner obtained "splendid well-developed prisms of perfectly pure aniline violet, which that chemist produced by operating on a very large scale." The chemical composition of this colour has not yet been established. The process of manufacture is as follows:—A cold and dilute solution of sulphate or any other salt of commercial aniline is mixed with a solution, also cold and dilute, of bichromate of potassium. The mixture is well stirred, and allowed to stand for ten or twelve hours. A black precipitate is produced, which is collected upon a filter, washed with cold water, and dried. The black matter is digested with light coal-tar oil, when a brownish-black tarry substance is dissolved from the colouring-matter obtained in the precipitate. The insoluble residue is then dried and digested with wood-spirit or alcohol, or indeed with any liquid capable of dissolving the colouring-matter. The clear solution is separated by filtration or decantation, and distilled in order to recover the alcohol or wood spirit; the residue left in the retort is Mr. Perkins' aniline violet.

The black precipitate, after having been washed with cold water, is extracted by a

Digitized by Google

prolonged ebullition with large quantities of water (sometimes acidulated with from one to two per cent. of acetic acid), an operation which effects the solution of the colouring-matter. The filtered solutions are concentrated as much as possible, and while boiling are precipitated by the addition of caustic soda. The precipitate is filtered off and washed for some time with an alkaline solution, which facilitates the extraction of the excess of bichromate of potash, and removes a reddish colouring-matter affecting the purity of the aniline violet. It is then treated with cold water until the alkali is removed, and the washings become coloured. The violet is thus obtained in the form of a paste.

The following processes have also been proposed for the production of aniline violet:—

1. Oxidation of an aniline salt by a solution of permanganate of potassium.—*Williams.*
2. Oxidation of an aniline salt by a solution of ferricyanide of potassium.—*Smith.*
3. Oxidation of a cold and dilute solution of hydrochlorate of aniline by a dilute solution of chloride of lime.—*Bolley, Beale, and Kirkman.*
4. Oxidation of a salt of aniline in an aqueous solution of peroxide of manganese.—*Kay.*
5. Oxidation of a salt of aniline by the peroxide of lead under the influence of an acid.—*Price.*
6. Oxidation of a salt of aniline by free chlorine or free hypochlorous acid.—*Smith.*
7. Oxidation of a salt of aniline by the double chloride of copper and sodium.—*Dale and Caro.*

The only processes which are employed industrially are those in which bichromate of potash, chloride of lime, and chloride of copper are used. The dyeing of silk or wool by means of aniline violet is a process of the easiest description.

Dyeing Silk.—An alcoholic solution of the violet purple is diluted with eight times its volume of hot water previously acidulated with tartaric acid. This liquid is poured into the dyeing-bath of cold water slightly acidulated. Through this the silk is passed until the required shade is attained. The tint is rendered bluish by means of indigo-carmine. Sulphuric acid added to the dye-bath causes the violet to assume a greyish shade. This may be increased until a very beautiful grey (*gris perle*) is obtained. This colour is much used by the silk-dyers of Lyons.

Dyeing Wool.—This is conducted at a temperature of 50° or 60° C., the dye-bath consisting simply of a dilute aqueous solution of colouring-matter, without any acid.

Printing upon Silk and Wool.—The paste of aniline violet is dissolved in about five times its weight of acetic acid (specific gravity, 1·060), and mixed with enough gum-water to form a printing material. The fabrics when printed are submitted to the action of steam, and then washed.

Dyeing Cotton.—Since cotton does not, like silk or wool, present any attraction for the aniline colours, the dyer employs albumin, soluble glutin, or tannin. In some cases the oxides of tin, of aluminium, of lead, or of antimony are used. Sulphuric acid has also the property of fixing the aniline violet on cotton. The animal or tannin mordants are printed on the cotton, which is steamed so as to fix it, and it is then dyed in an acidulated solution of the colour.

Violet Impérial.—This violet, which is essentially different from the mauve, is formed by modifications of the aniline reds and blues. It is produced thus:—Equal quantities of aniline and dry hydrochlorate of rosaniline are heated to a temperature of 180° C. for about four hours. MM. Girard and De Laire first patented this colour, and on account of its great beauty it is much used. It is not, however, so permanent as the mauve. Mr. E. C. Nicholson forms another violet by aniline red in a suitable apparatus to a temperature between 200° and 215° C. This mass is exhausted with acetic acid, and the deep-violet solution diluted with enough alcohol to give to the dye a convenient strength.

Aniline violet resists the action of light to a very considerable extent, although Chevreul has shown that it is inferior in this respect to either madder, cochineal, or indigo.

ANILINE YELLOW. In the preparation of aniline red there arises a great number of secondary products. Amongst others, a yellow colouring-matter has been separated by Mr. Nicholson and examined by Dr. Hofmann. The name of *Chrysaniline* has been given to this very beautiful yellow colour, which has been proved to be a well-defined base. The preparation of chrysaniline is simple. The residue from which the rosaniline has been extracted is submitted for some time to a current of steam, when a quantity of the base passes into solution. Addition of nitric acid to this solution precipitates the chrysaniline in the form of a difficultly soluble nitrate.

Hofmann has shown that chrysaniline is intimately related to rosaniline and

Digitized by Google

leucaniline, only differing from the first by two equivalents, and from the second by four equivalents of hydrogen :—

Chrysaniline $C_{20}\ H_{17}\ N_3$.
Rosaniline $C_{20}\ H_{19}\ N_3$.
Leucaniline $C_{20}\ H_{21}\ N_3$.

Chrysaniline forms two series of salts, the greater number of which are well crystallised. The most remarkable salt of chrysaniline is the nitrate, which is so insoluble in water that nitric acid may be precipitated, even from a dilute aqueous solution, by means of the more soluble hydrochlorate or acetate of chrysaniline. These, when poured into a nitric solution, rapidly give rise to the formation of an orange-red chrysaniline precipitate of nitrate of chrysaniline. This chrysaniline and its salts dye silks and wools a splendid golden-yellow colour. Such is the general character of the aniline colours. They have been used as printing-inks, which are very permanent. See Watts' (Ure's) "Dictionary of Chemistry."

ANIMÉ. A resin of a pale brown yellow colour, transparent and brittle. It exudes from a large American tree, called by Piso, *jetaiba*; and by the Indians, *courbaril*. It appears to be a species of *hymenæa*. It occurs in pieces of various sizes, and it often contains so many insects belonging to living species, as to have merited its name, as being animated. It contains about a fifth of 1 per cent. of a volatile oil, which gives it an agreeable odour. Alcohol does not dissolve the genuine animé, as I have ascertained by careful experiments, nor does caoutchoucine; but a mixture of the two, in equal parts, softens it into a tremulous jelly, though it will not produce a liquid solution. When reduced to this state, the insects can be easily picked out, without injury to their most delicate parts. On the contrary, Dr. R. D. Thomson says, animé resin is distinguished from copal by its ready solubility in alcohol; and that when digested in cold alcohol a portion remains undissolved, which may be dissolved in hot alcohol, from which it crystallises on cooling. Sir R. Kane gives $C^{10}\ H^{13}\ O$ as the composition of this gum-resin.—*Watts' Dictionary of Chemistry.*

The specific gravity of the different specimens of animé varies from 1·054 to 1·057. When exposed to heat, in a glass retort over a spirit flame, it softens, and, by careful management, it may be brought into liquid fusion without discoloration. It then exhales a white vapour of an ambrosial odour, which being condensed in water, and the liquid being tested, is found to be succinic acid.

It is extensively used by the varnish makers, who fuse it at a pretty high heat, and in this state combine it with their oils or other varnishes. It is also employed, on account of its agreeable smell when burning, in the manufacture of pastilles.

ANISEED. (*Anis*, Fr.; *Anis*, Germ.) The fruit or seed of the *pimpinella anisum*, largely cultivated in Malta, Spain, and Germany; used in the preparation of the oil of anise (*oleum anisi*), the spirit of anise (*spiritus anisi*), and anise water (*aqua anisi*). It is also used in cordials. In 1855, 963 cwts. were imported. The *oleum badiani*, or the *oil of star anise* (*illicium anisatum*), has the colour and taste of the oil of anise; but it preserves its fluidity at 35·6° F. It is sometimes fraudulently substituted for *oleum anisi.—Pereira.*

ANISIDINE. ($C^{14}\ H^9\ NO^2$) An alkaloid produced by the action of reducing agents (such as hydrosulphuric acid or protacetate of iron) on nitranisole.—C. G. W.

ANKER. A liquid measure of Amsterdam, which contains 32 gallons English. During the war, when communication with Holland was constant, and sailors and soldiers were constantly passing from one country to the other, the anker was as commonly used as a measure in our seaports as in those of Holland. The anker of brandy was frequently smuggled into this country,

ANNEALING or NEALING. (*Le recuit*, Fr.; *das Anlassen*, Germ.) A process by which glass is rendered less frangible; and metals which have become brittle, either in consequence of fusion or long-continued hammering, are again rendered malleable. When a glass vessel is allowed to cool immediately after being made, it will, if a small splinter of flint, or an angular fragment of quartz, is dropped gently into it, make it sometimes immediately, sometimes after a few minutes, fly to pieces with great violence. This extreme fragility is prevented by annealing, or placing the vessels in a hot oven, where they take several hours, or even some days, to cool.

Similar phenomena are exhibited in a higher degree by glass-tears, or Prince Rupert's drops, procured by letting drops of melted glass fall into cold water. Their form resembles that of a pear, rounded at one extremity, and tapering to a very slender tail at the other. If a part of the tail be broken off, the whole drop flies to pieces with a loud explosion; and yet the tail of a drop may be cut away by a glass-cutter's wheel, or the thick end may be struck smartly with a hammer, without the fear of sustaining any injury. When heated to redness, and permitted to cool gradually in the open air, they lose these peculiarities, and do not differ sensibly from common glass.

The peculiar brittleness of unannealed glass is, by many manufacturers, referred to

Digitized by Google

the following conditions. The exterior surface of the glass cooling quicker than the layers of glass beneath, the two portions of glass are supposed to be in different degrees of tension; as they technically express it, *a stretched skin of glass* is formed; and as the arrangement of the particles is different in this film from their disposition in those parts which have cooled more slowly, there is a constant tendency to fracture, the slightest scratch upon this "skin" disturbing the entire molecular arrangement.

If any mass of glass or of metal cools rapidly, there will be, according to the thickness of the mass, a greater or less difference between the arrangement of the constituent particles on the outer and inner sections. The process of annealing secures an equal arrangement throughout the mass.

When metals have been extended to a certain degree under the hammer, they become brittle, and incapable of being further extended without cracking. In this case the workman restores their malleability, sometimes by annealing, or, in other cases, by heating them red-hot and allowing them to cool slowly. The rationale of this process seems to be, that the hammering and extension of the metal destroys the kind of arrangement which the particles of the metal had previous to the hammering; and that the annealing, by softening the metal, enables it to recover its original structure.

Of late years a mode has been discovered of rendering cast iron malleable, without subjecting it to the action of puddling. The process is somewhat similar to that employed in annealing glass. The metal is kept imbedded in ground charcoal, or in powdered hæmatite, for several hours at a high temperature, and then allowed to cool slowly. In this manner vessels are made of cast iron which can sustain considerable violence without being broken. See IRON, MALLEABLE.

ANTHRACITE. (ἄνθραξ, coal.) A variety of coal containing a larger proportion of carbon and less bituminous matter than common coal.—*De la Beche.*

"We see the same series of coal beds becoming so altered in their horizontal range, that a set of beds *bituminous* in one locality is observed gradually to change into *anthracitic* in another. Taking the coal measures of South Wales and Monmouthshire, we have a series of accumulations in which the coal beds become not only more anthracitic towards the west, but also exhibit this change in a plane which may be considered as dipping S. S. E. at a moderate angle, the amount of which is not yet clearly ascertained, so that in the natural sections afforded we have bituminous coals in the high grounds and anthracitic coals beneath. This fact is readily observed either in the Neath or Swansea valleys, where we have bituminous coals on the south and anthracite on the north; and more bituminous coal beds on the heights than beneath, some distance up these valleys—those of the Nedd and Tawe. Though the terms bituminous coal and anthracite have been applied to marked differences, the changes are so gradual that there is no sudden modification to be seen. To some of the intermediate kinds the term 'free burning' has been given, and thus three chief differences have been recognised."—*Memoirs of the Geological Survey.*

The term *Culm* is applied both to an inferior kind of anthracite only worked for making lime, or for mixing with clay, and to the small pieces of good anthracite obtained in working the true anthracite beds. It is also called *Blind Coal, Glance Coal,* and *Kilkenny Coal.*

The term *Culm* is applied generally to anthracite in our parliamentary returns.

There are three very distinct "trades" in anthracite. There is, first, that where the coal is sold exactly as it is worked, "through and through," as it is termed, or *Through Culm,* which is used entirely for lime-burning. This coal is not of so pure a kind as that from which the large coal is picked out, and is sometimes called *Bastard Stone Coal.* The trade in the Neath district is entirely of this kind. In Swansea and Llanelly it is partly of this kind, and partly of the kind where the large coal is picked out, and sold as *Stone Coal* for the various purposes to which that coal is applied, leaving the small to be shipped, also for lime-burning purposes, under the name of *Stone Coal Culm.* In Pembrokeshire no "through culm" is shipped. There is one curious lot of 4,000 tons annually shipped in Swansea under the name of *Lambskin,* which is almost dust; it is sent to one market—Cardiganshire, where it is used entirely for mixing with clay; the mixture, under the name of *Fireballs,* being used for household purposes. This mixture, made of the ordinary *Stone Coal Culm,* is also very commonly used in parts of Pembrokeshire and Caermarthenshire.

Anthracite coal is obtained in this country at Bideford in Devonshire, at Walsall in Staffordshire, in the western divisions of the South Wales coalfield, in Ireland, and near Edinburgh. It is found abundantly in America. Professor H. D. Roger's "Transactions of American Geologists" states that in the great Apalachian coalfield, extending 720 miles, with a chief breadth of 180 miles, the coal is bituminous

Digitized by Google

towards the western limit, where it is level and unbroken, becoming anthracitic towards the south-west, where it is disturbed. Anthracitic coal is also found in the coal-fields of France, especially in the departments of Isère, the High Alps, Gard, Mayenne, and of Sarth; about 42,271,000 kilogrammes (of 2·2046 avoirdupois pounds each) are produced annually. Anthracite is also raised in Belgium.

Anthracite is not an original variety of coal, but a modification of the same beds which remain bituminous in other parts of the region. Anthracite beds, therefore, are not separate deposits in another sea, nor coal-measures in another area, nor interpolations among bituminous coals; but the bituminous beds themselves, altered into a natural coke, from which the volatile bituminous oils and gases have been driven off.—*J. P. Lesley, on Coal.*

Anthracite—now exclusively used for iron-making, steam-engines, and for domestic purposes in the United States—was some 50 years since regarded as incombustible refuse, and thrown away.

The following analyses of bituminous and anthracite coals will sufficiently show the differences:—

The calorific value of anthracite coal is well shown by the following results from Dr. Fyfe's experiments to compare Scotch and English bituminous coals with anthracite, in regard to their evaporative power, in a high-pressure boiler of a 4-horse engine having a grate with 8·15 square feet of surface; also in a waggon-shaped copper boiler, open to the air, surface 18 feet, grate 1·55.

Kind of Fuel employed.	Pounds burnt per Hour on the Grate.	Duration of the Trial in Hours.	Temperature of the Water.	Pounds of Water evaporated from the Initial Temperature by 1 lb. of Coal.	Pounds of Water at 212° from 1 lb. of Coal.	Coal per Hour on 1 Square Foot of Grate.	Time in Seconds of consuming 1 lb. of Coal.	Pounds evaporated per Hour from each Square Foot of Surface.	Remarks.
Middlerig Scotch coal.	81·33	9	45°	6·66	7·74	10·00	44·27	- -	Pressure 17 lbs. per sq. inch.
Scotch coal, different variety from preceding.	108	5	170	6·62	6·89	13·25	33·33	- -	Ditto.
ANTHRACITE - -	47·94	8½	45	8·73	10·10	5·89	75·09	- -	Ditto.
Scotch coal, from near Edinburgh.	8·24	8½	50	5·38	6·90	5·31	436·89	3·15	Low pressure, open copper boiler.
English bituminous coal.	6·07	8·4	50	7·84	9·07	3·91	503·08	3·06	Ditto.

Space will not admit of our entering fully into the question of the evaporative power of anthracite; but its advantages under certain conditions are fully established.

In this country anthracite coal is used in the manufacture of iron in the following furnaces:—

Ystalyfera in Glamorganshire	6	furnaces	in blast in 1864
Yniscedwyn in Brecknockshire	1	„	„
Bryn Amman in Caermarthenshire	1	„	„
Kilgetty in Pembrokeshire	1	„	„

The quantity of anthracite iron made in 1864 being 26,565 tons.

Anthracite Coal worked in South Wales in 1864 amounted to 509,475 tons. viz.—

Pembrokeshire	146,000 tons.
Carmarthenshire and Glamorganshire	363,475 „
	509,475 „
Anthracite shipped:	
Pembrokeshire at Saundersfoot &c.	82,000 „
Swansea	67,000 „
Briton Ferry	68,000 „
Llanelly and Pembray	130,000 „
Total shipped in 1864	347,000 „
Total quantity used at ironworks, for household purposes, and sent off by railway to be used principally for malting	162,475 „
Total	509,475 „

In the anthracite districts of South Wales the produce was, according to some local returns—in 1855, 997,500 tons; and in 1856, 965,500 tons.

There are reasons for believing that these returns were in excess of the real quantities produced, but considerable experiments were being made in those years upon the use of anthracite for melting iron.

Professor W. R. Johnson, of Pennsylvania College, informs us that fourteen furnaces using anthracite for the production of iron were in use in the United States.

The following table shows the progress of production in America of anthracite from 1840 to 1860, inclusive, from Schuylkill, Lehigh, and Wyoming:—

Digitized by Google

Year.	Tons.	Increase per Year. Tons.
1840	864,384	45,982
1841	950,973	86,589
1842	1,108,418	157,445
1843	1,263,598	155,180
1844	1,630,850	367,252
1845	2,013,013	382,163
1846	2,344,005	330,992
1847	2,882,300	538,595
1848	3,089,238	206,938
1849	3,217,641	128,403
1850	3,321,136	103,495
1851	4,329,530	1,008,394
1852	4,899,975	570,445
1853	5,097,144	197,169
1854	5,831,834	734,690
1855	6,486,097	654,263
1856	6,751,542	265,445
1857	6,431,379	320,163 decrease.
1858	6,819,881	388,502 increase.
1859	7,838,439	18,558
1860	8,500,550	662,111
1861	7,424,530	76,120 decrease.
1862	7,527,356	102,826 increase.

Since 1862 a reliable statement has not been obtainable.

The progress of the annual consumption of anthracite in the United States was thus stated in the *Science of New York Exhibition* :—

1820 - - - - - -	about	330	tons.
1825 - - - - - -	„	35,000	„
1830 - - - - - -	„	176,000	„
1835 - - - - - -	„	561,000	„
1840 - - - - - -	„	865,000	„
1845 - - - - - -	„	2,023,000	„
1850 - - - - - -	„	3,357,000	„
1853 - - - - - -	„	5,195,000	„

ANTELOPE HORN is used occasionally for ornamental knife-handles. See HORN.

ANTICHLORE. A term employed by bleachers to the means of obviating the pernicious after-effects of chlorine upon the pulp of paper, or stuffs, which have been bleached therewith. Manufacturers have been in the habit of using sulphite of soda, whose action upon the adhering bleaching salt, which cannot be removed by washing, gives rise to the formation of sulphate and hydrosulphate of soda and chloride of sodium. Chloride of tin has been recommended by some chemists for this purpose.

ANTI-GUGGLER. A small syphon of metal, which is inserted into the mouths of casks, or large bottles called carboys, to admit air over the liquor contained in them, and thus to facilitate their being emptied without agitation or a guggling noise.

ANTI-ATTRITION, or, ANTI-FRICTION COMPOSITION. Various preparations have been, from time to time, introduced for the purpose of removing, as much as possible, the friction of machinery. Black lead, or plumbago, mixed with a tenacious grease, has been much employed. Peroxide of iron, finely divided hæmatite, &c., have also been used.

A composition employed at Munich is reported to have been used with success and economy to diminish friction of machinery. It consists of ten and half parts of pure hogs' lard fused with two parts of finely pulverised and sifted plumbago. The lard is first to be melted over a moderate fire, then a handful of the plumbago thrown in, and the materials stirred with a wooden spoon until the mixture is perfect; the rest of the plumbago is then to be added, and again to be stirred until the substance is of uniform composition; the vessel is then to be removed from the fire, the motion being continued until the mixture is quite cold. The composition, in its cold state, was applied to the pivots, the teeth of wheels, &c., by a brush, and seldom more than once in 24 hours.*

* Ann. des Mines, xi. 79.

Digitized by Google

It was found that this composition replaced the oil, tallow, and tar in certain iron-works with economy, saving about four-fifths of the cost of these articles.

ANTI-FRICTION METAL. Tin and pewter are often employed as anti-friction metals for the bearings of locomotive engines. One half of each tin and copper is now used at some of the large railway works.

Babbet's metal is prepared by taking about fifty parts of tin, five of antimony, and one of copper.

Tin, or pewter, used alone, owing to its softness, spreads out and escapes under the superincumbent weight of the locomotive, or other heavy machinery. It is usual, therefore, to add antimony, for the purpose of giving these metals hardness.

Fenton's Anti-friction metal, which is much employed, is a mixture of tin, copper, and spelter. Its advantages are stated to be cheapness in first cost, low specific gravity, being 20 per cent. lighter than gun metal; and being of a more unctuous or soapy character than gun metal, less grease or oil is required.

The softer metal is often supported by brasses cast of the required form, the tin alloy being cast upon them. The brasses, or bearings, being properly tinned, and an exact model of the axle having been turned, the parts are heated, put together in their relative positions, luted with plastic clay, and the fluid anti-friction metal poured in, which then becomes of the required form, and effectually solders the brass.

The following compositions are recommended to railway engineers as having been employed for several years in Belgium. In those cases where the objects are much exposed to friction, 20 parts of copper, 4 of tin, 0·5 of antimony, and 0·25 of lead. For objects which are intended to resist violent shocks, 20 parts of copper, 6 of zinc, and 1 of tin. For those which are exposed to heat, 17 parts of copper, 1 of zinc, 0·5 of tin, and 0·25 of lead. The copper is added to the fused mass containing the other metals. See ALLOY and KINGSTON'S METAL; ANTIMONY.

ANTIMONY. (*Antimoine*, Fr.; *Spiessglanz*, or *Spiessglas*, Germ.) The only ore of this metal found in sufficient abundance to be smelted is the sulphide or sulphuret, formerly called crude antimony.

Antimony occurs with numerous ores of lead and silver, of nickel, &c., but the most important ore of antimony is the sulphuret (Stibnite, or Grey Antimony), which forms the chief and most common source of the antimony of commerce, and of the greater number of the pharmaceutical preparations of that metal. Antimony is not at present produced in this country, but in the last century it was mined extensively.

Antimony.—"Pendant quelque temps, l'antimoine a été exploité très-activement en Angleterre, dans les comtés de Cornouailles et de Devon, où la mine de Huel Boys produisait annuellement, vers 1775, 400 quintaux métriques de métal. Pendant quelque temps aussi, de riches mines d'antimoine ont été exploitées en Espagne, dans la province de la Manche: aujourd'hui elles ne donnent plus de produits."*

Stibnite, or Grey Antimony Ore, sometimes occurs compact, but usually in very long prismatic or acicular crystals, or in a fibrous form. It is of a lead or steel-grey colour, sometimes with an iridescent lustre, sectile and flexible when in thin laminæ. It may be distinguished from a similar ore of manganese by its perfect diagonal cleavage and easy fusibility. Grey antimony is composed of antimony 74, sulphur 26. It fuses readily in the flame of a candle, to which it imparts a greenish tint. On charcoal, in the flame of a blowpipe, it gives out a strong smell of sulphur, with white fumes, and yields a white slag. When pure, it is perfectly soluble in muriatic acid. Its specific gravity is 4·5.

The most celebrated localities of this ore are Felsobanya, Schemnitz, and Kremnitz, in Hungary, where it occurs in diverging prisms several inches long. It is also found in the Hartz, at Andreasberg, in Hungary, in Cornwall, at the old Trewetha mine, and abundantly in Borneo.

This ore was called by the ancients πλατυόφθαλμον — πλατὺς, *broad*, ὀφθαλμὸς, *eye* — from the use to which it was applied in increasing the apparent size of the eye, as is still practised among oriental nations, by staining the upper and under edges of the eyelids. It was also used as a hair dye and to colour the eyebrows.

It was the Lupus Metallorum of the alchemists. Crude antimony is obtained from it by simple fusion, and from this product the pure metal is extracted.

The other principal ores of antimony are the following:—

Native Antimony is a mineral of a tin-white colour and streak and a metallic lustre, and sometimes contains silver, iron, and arsenic, with which last it is commonly associated. It is brittle, and possesses a specific gravity of 6·62 to 6·72. It is generally lamellar, sometimes botryoidal, or reniform. Before the blowpipe it soon melts, and continues to burn after the heat is removed; but if the heat be continued, it evaporates in white fumes, and is redeposited round the globule.

Native antimony occurs at Sahlburg in Sweden, Andreasberg in the Hartz, Allemont in Dauphiny, in Mexico, &c.

* Encyclopédie Nouvelle. Paris, 1839.

Digitized by Google

Arsenical Antimony also occurs at Allemont, in the Hartz, and elsewhere, in reniform and amorphous masses, with a finely granular or a curved lamellar structure. It is composed of arsenic 62·15, antimony 57·85. It possesses a metallic lustre, and a reddish-grey or tin-white lustre. Its specific gravity is 6·2.

Oxide of Antimony (*Cervantite*) occurs, associated with grey antimony (of which it is an altered form), at Cervantes, in Spain, in Hungary, and the Auvergne. It is found in octahedral crystals, and in radiating fibrous crystals in the province of Constantina, in Algeria (*Senarmontite*), also at Perneck, in Hungary. It occurs as a crust or powder, or in acicular crystals, with a greasy or earthy lustre, and of a pale yellow or nearly white colour. Specific gravity = 40·8. It is composed of antimony 80·1, oxygen 19·9; but frequently it contains an admixture of iron, carbonate of lime, &c. It is soluble in muriatic acid.

White Antimony (*Valentinite*) is the result of the alteration of grey antimony, native antimony, and other ores of that metal. It possesses a shining pearly lustre and a snow-white colour, but is sometimes pinkish, or ash-grey, or brownish. It affords a white streak. It is composed of antimony 84·32, oxygen 15·68 Specific gravity = 5·56. It is found in tabular crystals in veins traversing the primary rocks at Przibram in Bohemia, near Freyberg in Saxony, Allemont in Dauphiny, &c.

Red Antimony (*Kermesite*) is a compound of oxide of antimony 30·2, and sulphide of antimony 69·8, or antimony 74·45, oxygen 5·29, and sulphur 20·49.

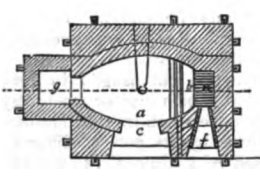
It occurs generally in capillary six-sided prismatic crystals of a cherry-red colour, affording a brownish-red streak. It has a specific gravity of from 4·5 to 4·6.

It is feebly translucent, and possesses an adamantine lustre. It occurs at Walaczka in Hungary, Braunsdorf in Saxony, and at Allemont in Dauphiny.

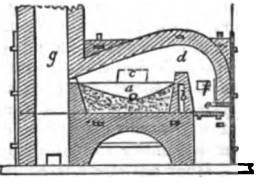
In treating the ores to obtain the metal, the first object is to separate the gangue, which was formerly done by filling crucibles with the mixed materials, placing them on the hearth of an oven, and exposing them to a moderate heat. As the sulphide easily melts, it ran out through a hole in the bottom of the crucible into a pot placed beneath, and out of the reach of the fire. But the great loss from the breakage of the crucibles has caused another method to be adopted. In this the broken ore, being sorted, is laid on the bottom of a concave reverberatory hearth, where it is reduced.

Figs. 65 and 66 represent a wind or flame furnace, for the reduction of antimony.

65



66



The hearth is formed of sand and clay solidly beat together, and slopes from all sides towards the middle, where it is connected with the orifice *a*, which is closed with dense coal-ashes; *b* is the air channel up through the bridge; *c*, the door for introducing the prepared ore, and running off the slags; *d*, the bridge; *e*, the grate; *f*, the fire or fuel-door; *g*, the chimney. With 2 or 3 cwts. of ore, the smelting process is completed in from 8 to 10 hours. The metal thus obtained is not pure enough, but must be fused under coal dust, in portions of 20 or 30 pounds, in crucibles placed upon a reverberatory hearth.

To obtain antimony free from iron, it should be fused with some antimonic oxide in a crucible, whereby the iron is oxidised and separated. The presence of arsenic in antimony is detected by the garlic smell, emitted by such an alloy when heated at the blowpipe; or, better, by igniting it with nitre in a crucible; in which case insoluble antimonite and antimoniate of potash will be formed along with soluble arseniate. Water digested upon the mixture, filtered, and then tested with nitrate of silver, will afford the brown-red precipitate characteristic of arsenic acid.

According to Berthier, the following materials afford, in smelting, an excellent product of antimony. From 100 parts of sulphide, 60 of protoxide of iron from the shingling or rolling mills (*hammerschlag*), 45 to 50 of carbonate of soda, and 10 of charcoal powder, from 65 to 70 parts of metallic antimony or regulus should be obtained. Glauber salts may be used advantageously instead of soda. Another formula is, 100 parts of sulphide of antimony, 42 of metallic iron, and 10 of dry sulphate of soda. The product thence is said to be from 60 to 64 parts of metal.

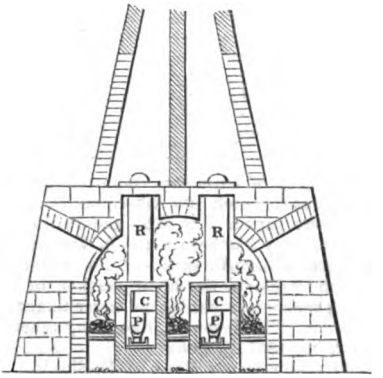
In the works where antimonial ores are smelted, by means of tartar (argol, bitartrate of potash), the alkaline scoriæ which cover the metallic ingots are not rejected as useless, for they hold a certain quantity of antimonial oxide in combination —a property of the potash flux which is propitious to the purity of the metal. These

Digitized by Google

scoriæ, consisting of sulphide of potassium and antimoniate of potash, being treated with water, undergo a reciprocal decomposition; the elements of the water act on those of the sulphide, and the resulting alkaline hydro-sulphide reacts on the antimonial solution so as to form a species of *kermes mineral*, which precipitates. This is dried, and sold at a low price as a veterinary medicine under the name of *kermes, by the dry way.*

At Malbosac, in the department of Ardèche, in France, the separation of the sulphide of antimony from its associated gangue is effected by means of a peculiar apparatus (see *fig.* 67). The mineral is placed in large retorts, RR, of which four are set in each furnace. An aperture is left at the bottom of each of these cylinders, which corresponds with a similar opening by which they are supported. Beneath these, in the chambers CC, are placed earthen pots, PP, in which is received the melted sulphide as it descends through the openings in the cylinders. The fuel consumed on the grate consists of fir wood; and the sulphide obtained is converted into metallic antimony by roasting in a reverberatory furnace, and subsequent reduction by a mixture of 20 per cent. of powdered charcoal which has been saturated with a strong solution of the carbonate of soda.

67



Metallic antimony, as obtained by the preceding process, is the antimony of commerce, but is not absolutely pure; containing frequently minute portions of iron, lead, and even arsenic, the detection and separation of which belong to the sciences of chemistry and pharmacy; but considerable purity may be secured by fusing the metal, mixed with a little of its sulphide and some carbonate of soda, repeatedly in a crucible. From 100 parts of the impure metal in this way 94 of pure antimony are obtained. The addition of sulphide serves the purpose, making fluid compounds of the sulphides of iron, arsenic, and copper, with the soda. Wöhler purifies antimony completely from arsenic (not from iron and copper) by deflagrating 10 parts of the crude ore with 12 of nitre and 15 of carbonate of soda; washes away the arsenic salt, and then smelts the residuary antimoniate of potash with black flux. Lead can be separated only by the humid analysis.

Antimony is a brittle metal, of a silvery white colour, with a tinge of blue, a lamellar texture, and crystalline fracture. When heated at the blowpipe, it melts with great readiness, and diffuses white vapours, possessing somewhat of a garlic smell. If thrown in this melted state on a flat sheet of paper, the globule sparkles and bursts into a multitude of small spheroids, which retain their incandescence for a long time, and run about on the paper, leaving traces of the white oxide produced during the combustion. When this oxide is fused with borax, or other vitrifying matter, it imparts a yellow colour to it. Metallic antimony, treated with hot nitric acid in a concentrated state, is converted into a powder, called antimonious acid, which is altogether insoluble in the ordinary acid menstrua—a property by which the chemist can separate that metal from lead, iron, copper, bismuth, and silver. According to Bergmann, the specific gravity of antimony is 6·86; but that of the purest is 6·715. The alchemists had conceived the most brilliant hopes of this metal; the facility with which it is alloyed with gold, since its fumes alone render this most ductile metal immediately brittle, led them to assign to it a royal lineage, and distinguished it by the title of *regulus*, or the little king.

Its chief employment is in making the alloys called type metal, stereotype metal, music plates, and Britannia metal; the first consisting of 6 of lead and 2 of antimony; the second of 6 of lead and 1 of antimony; the third of lead, tin, and antimony; and the fourth also of lead, tin, and antimony, with occasionally a little copper, bismuth, and nickel. Antimony is much used in alloys with tin, tin and lead, and in some cases copper, in various proportions, for machinery bearings, instead of gun metal. In cases of rapid and continuous revolution, as the shafts of screw-steamers, these are found much better than gun metal. It is also used by the Ordnance in hardening bullets and shot.—*Watts' Dictionary of Chemistry.*

Melted with tin, antimony has of late been used as an antifriction alloy for railway axles, and other bearings; in metallic rings, or collars, for machinery. As this alloy is not so much heated by friction as the harder metals, less grease is consumed.

Sulphide of antimony imported into France in French ships pays a duty of 11 francs for each 100 kilogrammes; but, if in foreign vessels, 12 francs. Metallic antimony pays a duty of 26 and 28 francs for 60 centimètres.

Antimony has been found in Victoria, the antimony ore existing near Heathcote. Of this, Westgarth says:—"The antimony ore *appears to be unlimited in quantity*; but the value in the home market, of from 9*l.* to 10*l.* per ton, will not admit of its being touched as yet by the eager fingers of commerce, nor probably for some years to come. This resource, like many others, remains for the railway era."—*Westgarth's Victoria*, 1857, p. 114.

Professor Henry Rose, of Berlin, in a memoir on the natural, not oxidised, combinations of antimony and arsenic, gives the following analyses*:—

ANTISEPTICS. (From *ἀντί*, against; *σηπτός*, putrid.) Substances which prevent the spontaneous decomposition of animal and vegetable substances. These are chiefly the mineral acids — charcoal, chloride of lime, chlorine, culinary salt, nitre, spices, sugar, creosote, and yeast — which operate partly by inducing a change in the animal or vegetable fibres, and partly by combining with and rendering the aqueous constituent unsusceptible of decomposition. See FOOD; PROVISIONS, CURING OF; and PRESERVED MEATS.

ANVIL. A mass of iron, having a smooth and nearly flat top-surface of steel, upon which blacksmiths, and various other artificers, forge metals with the hammer. The common anvil is usually made of seven pieces: 1, the core, or body; 2, 3, 4, 5, the four corner-pieces, which serve to enlarge its base; 6, the projecting end, which has a square hole for the reception of the tail, or shank of a chisel, on which iron bars may be cut through; and 7, the beak, or horizontal cone, round which rods or slips of metal may be turned into a circular form, as in making rings. These six pieces are welded separately to the first, or core, and then hammered into a uniform body. In manufacturing large anvils, two hearths are needed, in order to bring each of the two pieces to be welded to a proper heat by itself; and several men are employed in working them together briskly in the welding state, by heavy swing hammers. The steel facing is applied by welding in the same manner. The anvil is then hardened by heating it to a cherry red, and plunging it into cold water — a running stream being preferable to a pool or cistern. The facing should not be too thick a plate; for, when such, it is apt to crack in the hardening. The face of the anvil is now smoothed upon a grindstone, and finally polished with emery and crocus, for all delicate purposes of art.

The blacksmith, in general, sets his anvil loosely upon a wooden block, and, in preference, on the root of an oak tree. The cutlers and file makers fasten their anvils to a large block of stone, their peculiar work rendering it an advantage to have the anvil fixed as firmly and solidly as possible.

The *whitesmith*, or *brightsmith*, when working at the anvil, unless the piece under the hammer should be very light, is assisted by a striker, who wields a sledge-hammer. In forging round articles, such as bolts, axles, &c., the smith makes use of swages — pieces of steel formed somewhat like hammer-heads — with a groove in one corresponding with a hollow in the other. In forging small spindles, the boss, or lower piece, is permanently fixed upon the anvil. For convenience in managing heavy articles, a crane is so fixed in the workshops, that the arm traverses between the fire and the anvil.

APPLE-TREE. (*Pyrus malus.*) The wood of the apple-tree is much used in the Tunbridge turnery manufacture, and the millwright employs the wood of the crab-tree for the teeth of mortise wheels.

APPLES. The fruit of the *Pyrus malus* (apple-tree). Employed in the manufacture of cider (*which see*).

APPLE WINE. Cider. Winckler finds that the wine from apples is distinguished from the wine from grapes by the absence of bitartrate of potash and of œnanthic acid, by its containing a smaller amount of alcohol and more tannin, but

Digitized by Google

especially by the presence of a characteristic acid, which he regards as lactic acid, notwithstanding that this opinion is not confirmed by the degree of solubility of its salts with oxide of zinc, lime, and magnesia. See CYDER.

AQUAFORTIS. Nitric acid, somewhat dilute, was so named by the alchymists on account of its strong solvent and corrosive operation upon many mineral, vegetable, and animal substances. It is still employed as the commercial name of nitric acid. See NITRIC ACID.

This acid has usually been obtained by mixing common nitre with green vitriol or sulphate of iron, and distilling, or by mixing nitre and clay or siliceous matter, and distilling over the nitric acid, leaving the alkali to unite with the earthy base.

It may, however, be usefully borne in mind, that this term of *aquafortis*, or *strong water* of the old chemist, was also applied to solutions which answered their special purposes. Thus Salmon, in 1685, gives the composition of aquafortis from certain mixtures of acids, not nitric, and salts, and distinctly refers to the Pharmacopœia for the other kind. This may be of service when applying old recipes for processes in the arts. Aquafortis did not always mean nitric acid.

AQUAMARINE is the name given to those varieties of beryl which are of clear shades of sky-blue or greenish-blue, like the sky. It occurs in longitudinally-striated hexagonal crystals, sometimes a foot long, and is found in the Brazils, Hindostan, and Siberia. See BERYL.

AQUA REGIA. *Royal water.* The name given by the alchymists to that mixture of nitric and muriatic acids which was best fitted to dissolve gold; it is now called *nitro-muriatic acid*, or *nitro-chlorohydric acid*, or *hypochloro-nitric acid.*

Aqua regia, prepared under different conditions, appears to give different results. Gay-Lussac observed that aqua regia, when heated in a water-bath, evolves a gaseous body which, dried and exposed to a frigorific mixture, separates into chlorine and a dark lemon-yellow liquid, boiling at 70° F. This yellow liquid was found to contain 69·4 per cent. of chlorine, the calculated quantity for the formula, NO^2Cl^2, being 70·2. Gay-Lussac refutes the assertion of E. Davy and Baudrimont, that the properties of aqua regia are due to its containing a compound of chlorine, nitrogen, and oxygen, and confirms the generally received view, that its action depends upon free chlorine. From the vapour evolved in the action of aqua regia upon gold, a liquid may be condensed which is nearly of the composition NO^2Cl^2, containing, however, no *free* chlorine.

AQUA VITÆ. The name given to alcohol when used as an intoxicating beverage. It has been the *aqua mortis* to myriads of the human race; and will, probably, ere long destroy all the native tribes of North America and Australia.

Dr. Ure's definition of the term is in every respect strictly correct; but it appears necessary to add to it the explanation, that it is derived from the alchymists who, having obtained—in all probability from the Arabian physicians, since Avicenna uses the term — the product by distillation of saccharine fermentation, *al-kohol* (alcohol), gave, upon the same principle as guided them in calling the nitro-muriatic acid *aqua regia*, the name of *aqua vitæ* to several ardent spirits; and it has been retained especially with reference to whisky and brandy.

ARABIC, GUM. Gum Arabic, exudes from several species of *acacia* and *prunus*; it is also found in the roots of the mallow, comfrey, and some other plants. Gum Arabic never crystallises, is transparent, and has a vitreous fracture.

ARABIN. The principal constituent of Gum Arabic. If gum is treated with hydrochloric and alcohol, the lime magnesia and potash, in combination, are decomposed, and the arabin is separated as a gum, exhibiting the properties of an acid. In the moist state it dissolves in cold water forming *mucilage*, from which it is precipitated by alcohol. After drying, it no longer dissolves, but swells into a gelatinous mass. Dried at 212° F. it has the composition $C^{12}H^{11}O^{11}$. See ACACIA, CERASINE, DEXTRINE, GUM.

ARAGONITE. So called from Aragon, in Spain, where it was first discovered. A carbonate of lime, crystallised in rhombic prisms, or in forms derived from the same. Sometimes written ARRAGONITE. See LIME.

ARBOR VITÆ. Several species of *thuja*, found in America and China, are called *arbor vitæ*. It is a light, soft, and fine-grained wood, which is used in several kinds of carpentry.

ARCH. As this dictionary is not intended to include articles connected with engineering or with architecture, it would be out of place to describe the conditions required to ensure the stability of the arch, which is manifestly one of great importance to the practical builder. (For the theory of the equilibrium of the arch, Gwilt's treatise on the subject should be consulted, or the article Arch, "Encyclopædia Britannica.") It simply remains to define the arch as a structure of stone or brick, supported by its own curve; or of wood or iron, supported by the mechanical arrangements of the work.

Digitized by Google

The curvature of an arch may vary very considerably. Where the arch is low, the circle it belongs to becomes very large: and the strength of arches varies greatly with their forms; they may be either segments of a circle, a parabola, an ellipse, an hyperbola, or a catenary.

The arch in architecture is the means of passing from one pillar to another; and we have the circular form, which was succeeded by the pointed arch, and all its modified forms of foliation, &c.

ARCHERY BOW. These are divided into the "*single-piece bow*" and the "*back* or *union bow.*"

The single-piece bow is made of one rod of hickory, lance-wood, or yew-tree, which last, if perfectly free from knots, is considered the most suitable wood.

The union bow is made of two or sometimes three pieces glued together. The "*back*" piece, or that furthest from the string, is of rectangular section, and always of lance-wood or hickory; the "*belly,*" which is nearly of semicircular section, is made of any hard wood that can be obtained straight and clean, as ruby-wood, rose-wood, green-heart, king-wood, snake-wood, &c. Sometimes the union bow is imitated by one solid piece of straight cocoa-wood of the West Indies (not that of the cocoa-nut palm), in which case the tough fibrous sap is used for the back. The Palmyrea is also used for bows. — *Holtzapffel.*

ARCHIL. (*Orseille*, Fr.; *Orseille*, Germ.; *Oricello*, Ital.) The name of archil is given to a colouring matter obtained, by the simultaneous action of the air, moisture, and an ammoniacal liquor, from many of the *lichens*, the most esteemed being the *lichen roccella.*

It appears in commerce in three forms: 1, As a pasty matter called *archil;* 2, as a mass of a drier character, named *persis;* and 3, as a reddish powder called *cudbear.*

The lichen from which archil is prepared is known also as the canary weed or orchilla weed. It grows in great abundance on some of the islands near the African coast, particularly in the Canaries and several of the Islands of the Archipelago. Its colour is sometimes a light and sometimes a dark grey.

There appears to be good evidence for supposing that archil was known to the Romans, and Beckmann is disposed to believe that the ancient Greeks were familiar with this dye. This ingenious and industrious author gives the following account of the modern introduction of the archil.

"Among the oldest and principal Florentine families is that known under the name of Oricellarii or Rucellarii, Ruscellai or Rucellai, several of whom have distinguished themselves as statesmen and men of letters. This family is descended from a German nobleman, named Ferro or Frederigo, who lived in the beginning of the 12th century. One of his descendants, in the year 1300, carried on a great trade in the Levant, by which he acquired considerable riches, and returning at length to Florence with his fortune, first made known in Europe the art of dyeing with archil. It is said that a little before his return from the Levant, happening to make water on a rock covered with this lichen, he observed that the plant, which was there called *respio* or *respo*, and in Spain *orciglia*, acquired by the urine a purple colour, or, as others say, a red colour. He, therefore, tried several experiments, and when he had brought to perfection the art of dyeing wool with this plant, he made it known at Florence, where he alone practised it for a considerable time, to the great benefit of the state. From this useful invention the family received the name of Oricellarii, from which at last was formed Rucellai." — *History of Inventions.*

For more than a century Italy possessed the exclusive art of making archil, obtaining the lichens from the islands of the Mediterranean. Teneriffe furnished annually 500 quintals (of 110 lbs. each) of lichen; the Canary Isles, 400; Fuerta Ventura, 300; Lancerot, 300; Gomera, 300; Isle of Ferro, 800. This business, in the islands of Teneriffe and Canary, belonged to the Crown of Spain, and in 1730 brought in a revenue of 1500 piastres. The farmers paid from 15 to 20 reals for the right to gather each quintal.

Since 1402 the largest quantity of the lichens for the preparation of archil has been obtained in the Canary Islands; a smaller quantity has, however, been procured from the Cape de Verde Islands. It is stated that the archil from the lichens of the latter place dye wool of a deeper colour than the archil from the Canaries, but that the dye is not so rich. The labour of collecting these lichens is very great, and men are exposed to the greatest risks, being suspended by cords over the face off stupendous cliffs. Upon the coasts of Spain, Scotland, and Ireland, the peasantry have for a very long period used lichens for the purpose of dyeing red.

The chemical constitution of archil was first investigated by M. Cocq, "Annales de Chimie," vol. lxxxi.; and subsequently, yet more extensively, by Robiquet, "Annales de Chimie," vol. xlii. 2nd series.

From the *Variolaria*, Robiquet obtained *Orcine*, by digesting the lichen in alcohol,

Digitized by Google

evaporating to dryness, dissolving the extract in water, concentrating the solution to the thickness of a syrup, and setting it aside to crystallise. It forms, when quite pure, colourless prisms, of a nauseous sweet taste, which fuse easily, and may be sublimed unaltered. Its formula is $C^{16}H^{8}O^{4}+3Aq.$ when sublimed; when crystallised from its aqueous solution it contains 5 Aq.

If orcine be exposed to the combined action of air and ammonia, it is converted into a crimson powder *orcëine*, which is the most important ingredient in the archil of commerce. *Orcëine* may be obtained by digesting dried archil in strong alcohol, evaporating the solution in a water-bath to dryness, and treating it with ether as long as anything is dissolved; it remains as a dark blood-red powder, being sparingly soluble in water or ether, but abundantly in alcohol. Its formula is $C^{16}H^{9}NO^{7}$.

Orcëine dissolves in alkaline liquors with a magnificent purple colour; with metallic oxides it forms lakes, also of rich purple of various shades. In contact with deoxidising agents, it combines with hydrogen, as indigo does, and forms leuc-orcëine, $C^{16}H^{9}NO^{7}+H$. When bleached by chlorine, a yellow substance is formed, *chlor*-orcëine, the formula of which is $C^{16}H^{9}NO^{7}+Cl$ analogous to the other. — *Kane.*

Dr. Schunk, by an examination of several species of Lecanora, has proved that, although under the influence of ammonia and of air, they ultimately produce orcëine, these lichens do not contain orcine ready formed, but another body, *Lecanorine*, which, under the influence of bases, acts as an acid, and is decomposed into orcine and carbonic acid. If lecanoric acid be dissolved in boiling alcohol, it unites with ether, forming lecanoric ether, which crystallises beautifully in pearly scales. In the *roccella tinctoria* and the *evernia prunastri* erytheric acid is found. By the oxidation of this acid *amarythrine* or *erythrine bitter* is formed. These substances have been carefully examined by Schunk, Stenhouse, and Kane. The chemical history of these and some other compounds is of great interest; but as they do not bear directly upon the manufacture of archil, or its use in dyeing, further space cannot be devoted to their consideration.

Kane found archil and litmus of commerce to contain two classes of colouring matters, as already stated, *orcine* and *orcëine*, derived from it. Beyond these there were two bodies, one containing nitrogen, *azoerythrine*, and the other destitute of nitrogen, *erythroleic* acid. This latter acid is separated from the other bodies present in archil by means of ether, in which it dissolves abundantly, forming a rich crimson solution. It gives with alkalis purple liquors, and with earthy and metallic salts coloured lakes.

Beyond those already named there are several other species of lichen which might be employed in producing an analogous dye, were they prepared, like the preceding, into the substance called *archil*. Hellot gives the following method for discovering if they possess this property. A little of the plant is to be put into a glass vessel; it is to be moistened with ammonia and lime-water in equal parts; a little muriate of ammonia (sal ammoniac) is added, and the small vessel is corked. If the plant be of a nature to afford a red dye, after three or four days the small portion of liquid which will run off on inclining the vessel, now opened, will be tinged of a crimson red, and the plant itself will have assumed this colour. If the liquor or the plant does not take this colour, nothing need be hoped for; and it is useless to attempt its preparation on the great scale. Lewis says, however, that he has tested in this way a great many mosses, and that most of them afforded him a yellow or reddish-brown colour; but that he obtained from only a small number a liquor of a deep red, which communicated to cloth merely a yellowish-red colour.

Prepared archil gives out its colour very readily to water, ammonia, and alcohol. Its solution in alcohol is used for filling spirit-of-wine thermometers; and when these thermometers are well freed from air, the liquor loses its colour in some years, as Abbé Nollet observed; but the contact of air restores the colour, which is destroyed anew, *in vacuo*, in process of time; but the watery infusion loses its colour, by the privation of air, in a few days; a singular phenomenon, which merits new researches.

The infusion of archil is of a crimson bordering on violet. As it contains ammonia, which has already modified its natural colour, the fixed alkalis can produce little change on it, only deepening the colour a little, and making it more violet. Alum forms in it a precipitate of a brown red; and the supernatant liquid retains a yellowish-red colour. The solution of tin affords a reddish precipitate, which falls down slowly; the supernatant liquid retains a feeble red colour.

The researches on the lichens, as objects of manufacture, by Westring, of Stockholm, are worthy of attention. He examined 150 species, among which he found several which might be rendered useful. He recommends that the colouring matter should be extracted in the places where they grow, which would save a vast expense in curing, package, carriage, and waste. He styles the colouring substance itself cudbear, persio, or turnsole; and distributes the lichens as follows:—1st. Those which,

Digitized by Google

left to themselves, exposed to moderate heat and moisture, may be fixed without a mordant upon wool or silk; such are the *L. cinereus, æmutonta, ventosus, corallinus, Westringii, saxatilis, conspassus, barbatus, plicatus, vulpinus*, &c.

2. Those which develope a colouring matter fixable likewise without mordant, but which require boiling and a complicated preparation; such are the lichens *subcarneus, dillenii, farinaceus, jubatus, furfuraceus, pulmonareus, cornigatus, cocciferus, digitatus, ancialis, aduncus*, &c. Saltpetre or sea-salt is requisite to improve the lustre and fastness of the dye given by this group to silk.

3. Those which require a peculiar process to develope their colour, such as those which become purple through the agency of stale urine or ammonia. Westring employed the following mode of testing:—He put 3 or 4 drachms of the dried and powdered lichen into a flask, moistened it with 3 or 4 measures of cold spring water, put the stuff to be dyed into the mixture, and left the flask in a cool place. Sometimes he added a little salt, saltpetre, quicklime, or sulphate of copper. If no colour appeared, he then moistened the lichen with water containing $\frac{1}{30}$th of sal ammoniac and $\frac{1}{10}$th of quicklime, and set the mixture aside in a cool place from 8 to 14 days. There appeared in most cases a reddish or violet coloured tint. Thus the *lichen cinereus* dyed silk a deep carmelite and wool a light carmelite; the *L. physodes* gave a yellowish-grey; the *pustulatus*, a rose red; *sanguinarius*, grey; *tartareus*, found on the rocks of Norway, Scotland, and England, dyes a crimson-red. Cudbear is made from it in Jutland by grinding the dry lichen, sifting it, then setting it to ferment in a close vessel with ammonia. The lichen must be of the third year's growth to yield an abundant dye; and that which grows near the sea is the best. It loses half its weight by drying. A single person may gather from 20 to 30 pounds a day in situations where it abounds. No less than 2,239,685 pounds were manufactured at Christiansand, Flekkefiort, and Fakrsund, in Norway, in the course of the six years prior to 1812. Since more solid dyes of the same shade have been invented, the archil has gone much into disuse.

To prepare archil, the lichens employed are ground up with water to a uniform pulp, and this is then mixed with as much water as will make the whole fluid; ammoniacal liquors from gas or from ivory-black works, or stale urine, are from time to time added, and the mass frequently stirred so as to promote the action of the air. The orcine or erythrine which exists in the lichen absorbs oxygen and nitrogen, and forms orcëine. The roccelline absorbs oxygen and forms *erythroleic acid*; these being kept in solution by the ammonia, the whole liquid becomes of an intense purple, and constitutes ordinary archil.—*Kane.*

Archil alone is not used for dyeing silk, unless for lilacs; but silk is frequently passed through a bath of archil, either before dyeing it in other baths or after it has been dyed, in order to modify different colours or to give them lustre. It is sufficient here to point out how white silks are passed through the archil bath. The same process is performed with a bath more or less charged with this colour, for silks already dyed.

Archil, in a quantity proportioned to the colour desired, is to be boiled in a copper. The clear liquid is to be run off quite hot from the archil bath, leaving the sediment at the bottom, into a tub of proper size, in which the silks, newly scoured with soap, are to be turned round on the skein-sticks with much exactness, till they have attained the wished-for shade. After this they must receive one beetling at the river.

Archil is, in general, a very useful ingredient in dyeing; but as it is rich in colour, and communicates an alluring bloom, dyers are often tempted to abuse it, and to exceed the proportions that can add to the beauty without at the same time injuring, in a dangerous manner, the permanence of the colours. Nevertheless, the colour obtained when solution of tin is employed, is less fugitive than without this addition: it is red, approaching to scarlet. Tin appears to be the only ingredient which can increase its durability. The solution of tin may be employed, not only in the dyeing bath, but for the preparation of the silk. In this case, by mixing the archil with other colouring substances, dyes may be obtained which have lustre with sufficient durability.

To dye wool with archil, the quantity of this substance deemed necessary according to the quantity of wool or stuff to be dyed, and according to the shade to which they are to be brought, is to be diffused in a bath of water as soon as it begins to grow warm. The bath is then heated till it be ready to boil, and the wool or stuff is passed through it without any other preparation except keeping that longest in which is to have the deepest shade. A fine gridelin, bordering upon violet, is thereby obtained; but this colour has no permanence. Hence archil is rarely employed with any other view than to modify, heighten, and give lustre to the other colours. Hellot says, that having employed archil on wool boiled with tartar and alum, the colour resisted the air no more than what had received no preparation. But he obtained from

Digitized by Google

herb archil (*l'orseille d'herbe*) a much more durable colour, by putting in the bath some solution of tin. The archil thereby loses its natural colour, and assumes one approaching more or less to scarlet, according to the quantity of solution of tin employed. This process must be executed in nearly the same manner as that of scarlet, except that the dyeing may be performed in a single bath.

Archil is frequently had recourse to for varying the different shades and giving them lustre; hence it is used for violets, lilacs, mallows, and rosemary flowers. To obtain a deeper tone, as for the deep *soupes au vin*, sometimes a little alkali or milk of lime is mixed with it. The suites of this browning may also afford agates, rosemary flowers, and other delicate colours, which cannot be obtained so beautiful by other processes.

The herb archil, just named, called especially *orcëille de terre*, is found upon the volcanic rocks of the Auvergne, on the Alps, and the Pyrenees.

These lichens are gathered by men whose whole time is thus occupied; they scrape them from the rocks with a peculiarly shaped knife. They prefer collecting the orcëille in rainy weather, when they are more easily detached from the rocks. They gather about 2 kilogrammes a day, or about 4½ pounds. When they take their lichens to the makers of archil or litmus for the purpose of selling them, they submit a sample to a test, for the purpose of estimating their quality. To this end they put a little in a glass containing some urine, with a small quantity of lime. As the lichens very rapidly pass into fermentation if kept in a damp state, and thus lose much of their tinctorial power, great care is taken in drying them; when dry they may be preserved without injury for some time.

Archil is perhaps too much used in some cloth factories of England, to the discredit of our dyes. It is said, that by its aid ⅓rd of the indigo may be saved in the blue vat; but the colour is so much the more perishable. The fine soft tint induced upon much of the black cloth by means of archil is also deceptive. One half pound of cudbear will dye one pound of woollen cloth. A crimson red is obtained by adding to the decoction of archil a little salt of tin (muriate), and passing the cloth through the bath after it has been prepared by a mordant of tin and tartar. It must be afterwards passed through hot water.

Dyeing with archil with the aid of oil has been patented by Mr. Lightfoot, on the same principle as has been so long used in the Turkey red cotton dye, who also has recourse to metallic and earthy bases. See CUDBEAR and LITMUS.

ARCHITECTURE. The art of constructing buildings, which involves the consideration of very dissimilar points.

1. UTILITY,— as it regards any specified object, as —
   - *a.* Domestic accommodation in a dwelling house.
   - *b.* Acoustic arrangements in all buildings intended for public purposes This consideration is entirely lost sight of by modern architects.
   - *c.* Ventilation, which is a matter upon which a very large amount of empiricism has been expended with exceedingly small results.

2. DURABILITY.— If we examine the walls of our ruined abbeys and castles, we shall find that the stones employed still retain the marks of the workman's tool; and that in numerous cases the ornamental work is as sharp as if it had been executed but yesterday. This should prove to us that the selection of stone was of great importance.

ARECA. A genus of palms, containing two species—1. The *Areca catechu*, producing the betel nut, which is so universally chewed in the East Indies. 2. The *Areca oleracea*, or cabbage palm; the cabbage is eaten in the West Indies, both raw and boiled; and the trunk, which is often 100 feet long, is used in Jamaica for water pipes, which are said to become, when buried, almost as hard as iron.

It is one of the most beautiful palm trees growing in India. It is chiefly cultivated in Malabar, Ceylon, and Sumatra. One tree will produce, according to situation, age, and culture, from 200 to 800 nuts.

The exports of the Areca nut from Ceylon have been of late years as follows:—

AREOMETER. An instrument to measure the densities of liquids. (See ALCOHOLOMETRY.) The principle will be well understood by remembering that any solid body will sink further in a light liquid than in a heavy one. The areometer is usually a glass tube, having a small glass bulb loaded with either shot or quicksilver, so as to set the tube upright in any fluid in which it will swim. Within the tube is placed a graduated scale: we will suppose the tube placed in distilled water, and the line cut by the surface of the fluid to be marked; that it is then removed and placed in strong alcohol—the tube will sink much lower in this, and consequently we shall have two extremities of an arbitrary scale, on which we can mark any intermediate degrees.

Digitized by Google

The areometer of Baumé is used in France, and the following scale is adopted by the French chemists: —

Specific Gravity Numbers corresponding with Baumé's Areometric Degrees.

ARENACEOUS. *Arena*, sand. Sandy. Rocks composed of particles of sand, or, as the grits and sandstones containing much sand are said to be *arenaceous*. If they contain lime they are called *arenaceo-calcarĕous*.

ARGILLACEOUS. Composed of clay, or clayey. This name is applied to all rocks composed of clay. The compound rocks are distinguished as *argillo-arenaceous* or *argillo-calcareous*. Argillaceous rocks, when breathed on, have a peculiar earthy odour, by which they may be distinguished.

ARGILLACEOUS EARTH. (*Argilla*, clay, Lat.) The earth of clay, called in chemistry, alumina, because it is obtained in greatest purity from alum. See ALUMINA, CHINA CLAY, CLAY, KAOLIN.

ARGOL, or ARGAL. (*Tartre*, Fr.; *Weinstein*, Germ.) This tartrate of potash is known in commerce as the white and red argol; the white being the crust let fall by white wines, which is of a pale pinkish colour, and the red the crust deposited from red wines, and of a dark red colour. See TARTAR, CREAM OF TARTAR, &c.

The Imports were in 1853, 32,936; 1854, 29,971; 1855, 18,466; 1856, 18,875 cwts. In 1864, they were greatly reduced, as shown below :—

ARICINE. ($C^{16}H^{26}N^2O^5$) An alkaloid discovered by Pelletier and Corriol in a cinchona bark from Arica in Peru. It is separated by the same process as quinine.

ARMENIAN BOLE. See BOLE.

ARMENIAN STONE. Commercial name for LAPIS LAZULI, which see.

ARNATTO, ARNOTTO, or ANNOTTO. (*Rocou* or *roucou*, Fr.; *Orleans*, Germ.) A somewhat dry and hard paste, brown without and red within. It is usually imported in cakes of two or three pounds weight, wrapped up in leaves of large reeds, packed in casks, from America, where it is prepared from the seeds of a certain tree, called the *arnatto tree*; it is the *Bixa orellana* of Linnæus.

The shrub producing the arnatto is originally a native of South America; it is now cultivated in Guiana, St. Domingo, and in the East Indies. In the "Annales de Chimie" we have the following description of the arnatto tree:—"The tree produces oblong bristled pods, somewhat resembling those of a chesnut. These are at first of a beautiful rose colour, but, as they ripen, change to a dark brown; and bursting open, display a splendid crimson farina or pulp, in which are contained from thirty to forty seeds, somewhat resembling raisin stones. As soon as they arrive at maturity, these pods are gathered, divested of their husks, and bruised. Their pulpy substance, which seems to be the only part which constitutes the dye, is then put into a cistern, with just enough water to cover it, and in this situation it remains for seven or eight days, or until the liquor begins to ferment, which, however, may require as many weeks, according to circumstances. It is then strongly agitated with wooden paddles or beaters, to promote the separation of the pulp from the seeds. This operation is continued until these have no longer any of the colouring matter adhering to them; it is then passed through a sieve, and afterwards boiled, the colouring matter being thrown to the surface in the form of scum, or, otherwise, allowed to subside: in either case, it is boiled in coppers till reduced to a paste, when it is made into cakes and dried."

Instead of this long and painful labour, which occasions diseases by the putrefaction induced, and which affords a spoiled product, Leblond proposes simply to wash the seeds of the bixa till they are entirely deprived of their colour, which lies wholly on their surface; to precipitate the colour by means of vinegar or lemon juice, and to boil it up in the ordinary manner, or to drain it in bags, as is practised with indigo.

The experiments which Vauquelin made on the seeds of the bixa, imported by Leblond, confirmed the efficacy of the process which he proposed; and the dyers ascertained that the arnatto obtained in this manner was worth at least four times more than that of commerce; that, moreover, it was more easily employed; that it required less solvent; that it gave less trouble in the copper, and furnished a purer colour.

Arnatto dissolves better and more readily in alcohol than in water, when it is introduced into the yellow varnishes for communicating an orange tint.

The decoction of arnatto in water has a strong peculiar odour, and a disagreeable taste. Its colour is yellowish-red, and it remains a little turbid. An alkaline solution renders its orange-yellow clearer and more agreeable, while a small quantity of a whitish substance is separated from it, which remains suspended in the liquid. If arnatto be boiled in water along with an alkali, it dissolves much better than when alone, and the liquid has an orange hue.

The acids form with this liquor an orange-coloured precipitate, soluble in alkalis, which communicate to it a deep orange colour. The supernatant liquor retains only a pale yellow hue.

When arnatto is used as a dye, it is always mixed with alkali, which facilitates its solution, and gives it a colour inclining less to red. The arnatto is cut in pieces, and boiled for some instants in a copper with its own weight of crude pearl ashes, provided the shade wanted do not require less alkali. The cloths may be afterwards dyed in this bath, either by these ingredients alone, or by adding others to modify the colour; but arnatto is seldom used for woollen, because the colours which it gives are too fugitive, and may be obtained by more permanent dyes. Hellot employed it to dye a stuff prepared with alum and tartar; but the colour acquired had little permanence. It is almost solely used for silks.

For silks intended to become aurora and orange, it is sufficient to scour them at the rate of 20 per cent. of soap. When they have been well cleansed, they are immersed in a bath prepared with water, to which is added a quantity of alkaline solution of arnatto more or less considerable, according to the shade that may be wanted. This bath should have a mean temperature between that of tepid and boiling water.

When the silk has become uniform, one of the hanks is taken out, washed, and wrung, to see if the colour be sufficiently full; if it be not so, more solution of

Digitized by Google

arnatto is added, and the silk is turned again round the sticks: the solution keeps without alteration.

When the desired shade is obtained, nothing remains but to wash the silk, and give it two beetlings at the river, in order to free it from the redundant arnatto, which would injure the lustre of the colour.

When raw silks are to be dyed, those naturally white are chosen, and dyed in the arnatto bath, which should not be more than tepid, or even cold, in order that the alkali may not attack the gum of the silk, and deprive it of the elasticity which it is desirable for it to preserve.

What has now been said regards the silks to which the aurora shades are to be given: but to make an orange hue, which contains more red than the aurora, it is requisite, after dyeing with arnatto, to redden the silks with vinegar, alum, or lemon juice. The acid, by saturating the alkali employed for dissolving the arnatto, destroys the shade of yellow that the alkali had given, and restores it to its natural colour, which inclines a good deal to red.

For the deep shades, the practice at Paris, as Macquer informs us, is to pass the silks through alum; and if the colour be not red enough, they are passed through a faint bath of brazil wood. At Lyons, the dyers who use carthamus sometimes employ old baths of arnatto for dipping the deep oranges.

When the orange hues have been reddened by alum, they must be washed at the river; but it is not necessary to beetle them, unless the colour turns out too red.

Shades may be obtained also by a single operation, which retain a reddish tint, employing for the arnatto bath a less proportion of alkali than has been pointed out.

Guhliche recommends to avoid heat in the preparation of arnatto. He directs it to be placed in a glass vessel, or in a glazed earthen one; to cover it with a solution of pure alkali; to leave the mixture at rest for 24 hours; to decant the liquor, filter it, and add water repeatedly to the residuum, leaving the mixture each time at rest for two or three days, till the water is no longer coloured; to mix all these liquors, and preserve the whole for use in a well-stopped vessel.

He macerates the silk for 12 hours in a solution of alum, at the rate of an eighth of this salt for one part of silk, or in a water rendered acidulous by the aceto-citric acid above described; and he wrings it well on its coming out of this bath.

Silk thus prepared is put into the arnatto bath quite cold. It is kept in agitation there till it has taken the shade sought for; or the liquor may be maintained at a heat far below ebullition. On being taken out of the bath, the silk is to be washed and dried in the shade.

For lighter hues, a liquor less charged with colour is taken; and a little of the acid liquor which has served for the mordant may be added, or the dyed silk may be passed through the acidulous water.

We have seen the following preparation employed for cotton velvet:—1 part of quicklime, 1 of potash, 2 of soda.

Of these a ley is formed, in which 1 part of arnatto is dissolved; and the mixture is boiled for an hour and a half. This bath affords the liveliest and most brilliant auroras. The buff (chamois) fugitive dye is also obtained with this solution. For this purpose only a little is wanted; but we must never forget that the colours arising from arnatto are all fugitive.

Dr. John found in the pulp surrounding the unfermented fresh seeds, which are about the size of little peas, 28 parts of colouring resinous matter, 26·5 of vegetable gluten, 20 of ligneous fibre, 20 of colouring extractive matter, 4 formed of matters analogous to vegetable gluten and extractive, and a trace of spicy and acid matters.

The Gloucestershire cheese is coloured with arnatto, in the proportion of one cwt. to an ounce of the dye: butter is sometimes coloured with it.

When used in calico printing, it is usually mixed with potash or ammonia and starch.

Arnatto was considered to contain two distinct colouring matters, a yellow and red, till it was shown by M. Preisser that one is the oxide of the other, and that they may be obtained by adding a salt of lead to a solution of arnatto, which precipitates the colouring matter. The lead is separated by sulphuretted hydrogen; and the substance being filtered and evaporated, the colouring matter is deposited in small crystals of a yellow-white colour. These crystals consist of *bixine*; they become yellow by exposure to the air, but if they are dissolved in water they undergo no change. When ammonia is added to *bixine*, with free contact of air, there is formed a fine deep red colour, like arnatto, and a new substance, called *bixeine*, is produced, which does not crystallise, but may be obtained as a red powder; this is coloured blue by sulphuric acid, and combines with alkalis, and is *bixine* with addition of oxygen. When arnatto, in the form of paste, is mixed from time to time with stale urine, it

Digitized by Google

appears probable that the improvement consists in the formation of *bixeine* from the *bixine* by the ammonia of the urine. It has hence been suggested that, to improve the colour of arnatto, it might be mixed with a little ammonia, and subsequently exposed to the air, previously to its being used for dyeing.

A solution of arnatto and potash in water is sold under the name of *Scott's Nankeen Dye.*

Flag arnatto paid a duty of 18*s.* 8*d.* per cwt., and the other sorts 5*l.* 12*s.*, previously to 1832. The duty was subsequently reduced to 1*s.* per cwt. on the former and 4*s.* on the latter. It was repealed in 1845. The *Imports* of roll and flag arnatto in 1863 were as follows :—

ROLL, 761 cwts, value £2,853.
FLAG, 2,507 cwts, value £10,111.

and in 1864, we received the quantities given from the countries named.

ARNICA. A genus of plants belonging to the Nat. Ord. *Compositæ*, and sub-order *Corymbifera*. The *Arnica Montana*, called Leopard's Bane, or Mountain Tobacco, is a native of the north of Europe, and of the Alps. The plant contains a volatile oil, *oil of Arnica*; and an alkaline bitter principle, *Arnicine*. It is used occasionally in medicine.

AROMATIC VINEGAR. (*Acetum aromaticum.*) This is a compound of strong acetic acid with certain powerful essential oils or aromatic herbs. The "Edinburgh Pharmacopœia" orders it to be made with, concentrated acetic acid, 1½ pints; rosemary and thyme dried, of each 1 oz.; lavender, also dried, ½ oz.; cloves, bruised, ½ drachm. Macerate for seven days, strain, and express strongly, and filter the liquor. *Henry's aromatic vinegar* is prepared by dissolving oils of cloves, lavender, rosemary, and the like, in concentrated acetic acid. Camphorated acetic acid is sometimes substituted for the *acetum aromaticum.* These preparations have been in great repute as prophylactics in contagious fevers. The name of "*Le vinaigre des quatre voleurs*" has been given to aromatic vinegar in France—it is said, from the confessions of four thieves who, during the plague at Marseilles, plundered the dead bodies with perfect impunity after protecting themselves with aromatic vinegar.

ARQUERITE. A silver amalgam from the mines of Arquerous, near Coquimbo. It occurs crystalline. Domeyko finds it to consist of silver 86·49, mercury 13·51.

ARRACK. A spirituous liquor from the East Indies. This term, or its corruption, *rack*, is applied to any spirituous liquor in the East. The true arrack is said to be distilled from *toddy*—the fermented juice of the cocoa-nut tree. It is, however, frequently distilled from rice and sugar fermented with the cocoa-nut juice.

ARROBA. A measure of capacity and weight in general use throughout all those parts of South America which ever belonged to Spain. It is also used in Manilla and the East. According to Spanish standard weight, it should be 25·36 lbs. English. As a wine measure it is equal to 3·54 imperial gallons; as an oil measure it is but 2·78 imperial gallons.

ARROPE. Sherry boiled to a syrup; used for colouring other wines.

ARROWROOT. (*Racine fléchière*, Fr.; *Pfeilwurz*, Germ.) The root of the *maranta arundinacea*, a plant which grows in the West Indies, and furnishes, by pounding in mortars and elutriation through sieves, a peculiar species of starch, commonly, but improperly, called arrow root. It is reckoned more nourishing than the starch of wheat or potatoes, and is generally also freer from peculiar taste or flavour. The fresh root consists, according to Benzon, of 0·07 of volatile oil; 26 of starch (23 of which are obtained in the form of powder, while the other 3 must be extracted from the parenchyma in a paste by boiling water); 1·58 of vegetable albumen; 0·6 of a gummy extract; 0·25 of chloride of calcium; 6 of insoluble fibrine; and 65·5 of water. This plant was brought from the Island of Dominica, by Colonel James

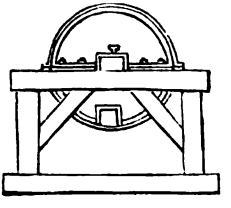
Digitized by Google

Walker, to Barbadoes, and there planted. From thence it was sent to Jamaica. The root appears to have been used by the Indians to yield a poison with which to smear their arrows, and hence its name.

This plant has been lately cultivated with great success, and its root manufactured in a superior manner, upon the Hopewell estate, in the Island of St. Vincent. It grows there to the height of about 3 feet, and it sends down its tap roots from 12 to 18 inches into the ground. Its maturity is known by the flagging and falling down of the leaves, which takes place when the plant is from 10 to 12 months old. The roots being dug up with the hoe are transported to the washing-house, where they are thoroughly freed from all adhering earth, and next taken individually in the hand, and deprived by a knife of every portion of their skins, while every unsound part is cut away. This process must be performed with great nicety, for the cuticle contains a resinous matter which imparts colour and a disagreeable flavour to the fecula which no subsequent treatment can remove. The skinned roots are thrown into a large cistern, with a perforated bottom, and there exposed to the action of a copious cascade of pure water till this runs off quite unaltered. The cleansed roots are next put into the hopper of the mill, and are subjected to the powerful pressure of two pairs of polished rollers of hard brass, the lower pair of rollers being set much closer together than the upper. (See *fig.* 67.) The starchy matter is thus ground into a pulp, which falls into the receiver placed beneath, and is thence transferred to large fixed copper cylinders, tinned inside, and perforated at the bottom with numerous minute orifices, like a kitchen drainer. Within these cylinders, wooden paddles are made to revolve with great velocity, by the power of a water-wheel, at the same time that a stream of pure water is admitted from above. The paddle arms beat out the fecula from the fibres and parenchyma of the pulp, and discharge it in the form of a milk through the perforated bottom of a cylinder. This starchy water runs along pipes, and then through strainers of fine muslin, into large reservoirs, where, after the fecula has subsided, the supernatant liquid is drawn off, and fresh water being let on, the whole is agitated and left again to repose. When the water ceases to remove anything from the arrow root, all the deposits of fecula are collected into one cistern, covered, and agitated with a fresh charge of water, and left until the following morning. The water being allowed to run off, the surface of the deposit is carefully scraped with German silver palette knives, to remove any impure or coloured parts, and the lower portions only are dried and prepared for the market. The greatest care is taken in drying; and when dry, the fecula is packed in tin cases for exportation.

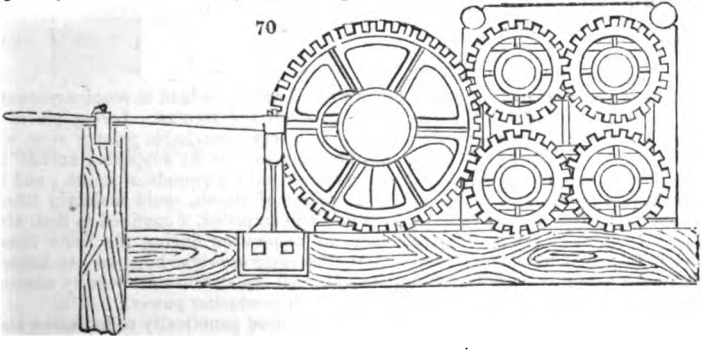
Fig. 68 (p. 192), plan of arrow root grinding mill, and two sets of copper cylinder washing machines, with the connecting machinery for driving them, the washing agitator being driven from the connecting shaft with leathern belts. *Fig.* 69, end elevation of copper washing cylinder, with press framing, &c. The washing cylinders are 6½ feet long and 3½ in diameter. The mill rollers are 3 feet long and 1 foot in diameter. *Fig.* 70, end elevation of arrow-root mill, with wheels and pinions, disengaging lever, &c.

69

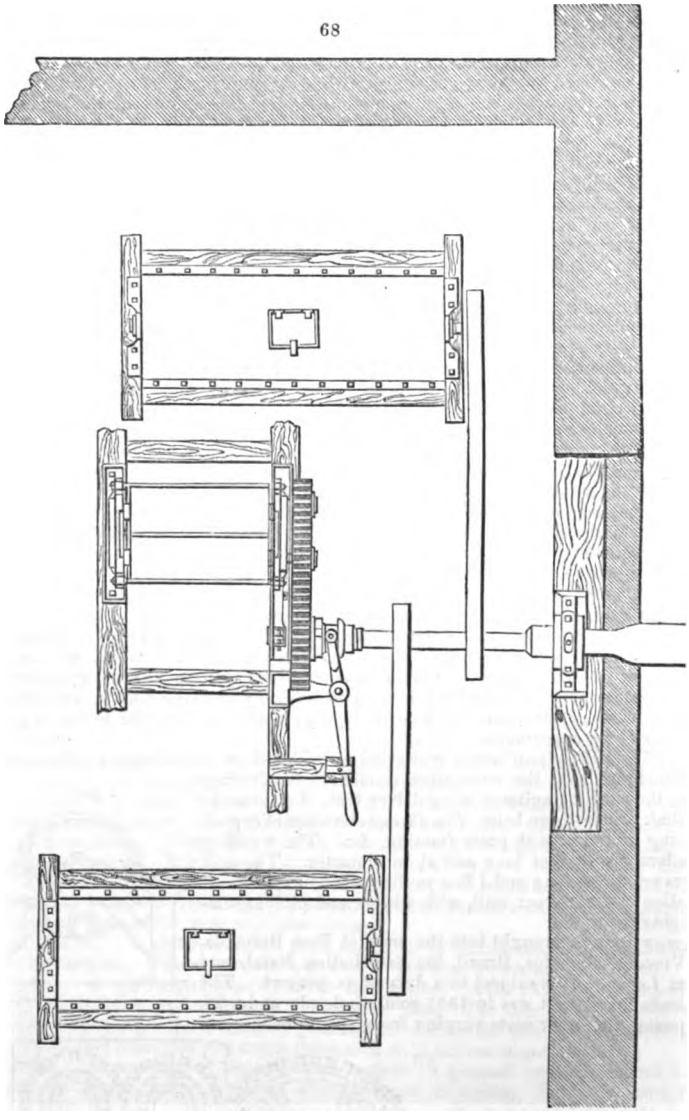


Arrow root is brought into the market from Bermuda, St. Vincent, Jamaica, Brazil, the East Indies, Natal, and Sierra Leone. It is subject to a duty of 4*s.* per cwt. The Bermuda arrow root was in 1865 sold wholesale at 1*s.* 2*d.* the pound, the other sorts varying from 2½*d.* to 6*d.*

70



Digitized by Google



The uses of arrow root are too well known and acknowledged to require recounting here. It is the most elegant and the richest of all the feculas. Liebig places the powers of arrow root, as a nutriment to man, in a very remarkable point of view, when he states that 15 pounds of flesh contain no more carbon for supplying animal heat by its combustion into carbonic acid in the system than 4 pounds of starch; and that if a savage, with one animal and an equal weight of starch, could maintain life and health for a certain number of days, he would be compelled, if confined to flesh alone, in order to procure the carbon necessary for respiration during the same time, to consume five such animals. The German Professor appears, however, to have lost sight of the nitrogen, or flesh-giving element. All the starches are readily converted into sugar and fat, but they are low in their flesh-producing power.

In commerce, the term *arrow root* is frequently used generically to indicate a starch or fecula, as:—

Digitized by Google

Portland arrow root, a white amylaceous powder, prepared in the Isle of Portland, from the *Arum vulgare*, the *common Cuckoo-pint*, called also *Wake-robin* and *Lords and Ladies*.

East India arrow root, prepared from the *Curcuma angustifolia*.

Brazilian arrow root, the fecula of *Jatropha manihot*.

English arrow root, the starch of the potato.

Tahiti arrowroot, the feculæ of *Tacca oceanica*, which is imported into London and sold as "arrow-root prepared by the native converts at the missionary stations in the South Sea Islands."

The presence of potato starch in arrow root, with which it is often adulterated, may be discovered by the microscope. Arrow root consists of regular ovoid particles of nearly equal size, whereas potato starch consists of particles of an irregular ovoid or truncated form, exceedingly irregular in their dimensions, some being so large as $\frac{1}{300}$th of an inch, and others only $\frac{1}{2000}$th. Their surfaces in the arrowroot are smooth, and free from the streaks and furrows to be seen in the potato particles by a good microscope. The arrow root, moreover, is destitute of that fetid unwholesome oil extractable by alcohol from potato starch. But the most convenient test is dilute nitric acid of 1·10 (about the strength of single aquafortis), which, when triturated in a mortar with the starch, forms immediately a transparent very viscid paste or jelly. Flour starch exhibits a like appearance. Arrow root, however, forms an opaque paste, and takes a much longer time to become viscid.

Imports and Exports.

In 1864 *we imported* as follows :—

	Cwts.	Computed real value.
From Portugal	1	£1
„ British Possessions in South Africa	1,534	5,092
„ the Bermudas	332	3,495
„ British West India Islands	13,958	33,603
„ Other Parts	975	1,699
	16,800	43,890

and our *exports* of Arrow root of Foreign and Colonial produce was :—

	Cwts.	Value.
Arrow root	2,188	£5,908

The irregular production of this article is shown in the following table of the produce of St. Vincent, as given by R. Montgomery Martin :—

	lbs.		lbs.
In 1828 it was	2,000	In 1832 it was	250
„ 1829 „	21,250	„ 1834 „	25,626
„ 1831 „	3,763	„ 1836 „	49,369

The exports, in recent years, from St. Vincent's have been as follows :—

	Barrels.	Tins.	Packages.	Value.
1858	6,128	23,983	620	£24,083
1859	8,078	16,552	495	27,576
1860	6,493	11,020	738	16,482
1861	6,430	11,847	314	£16,040
1862	3,747	1,787	6,804	9,328

The produce of the island of Bermuda was, in 1836, according to R. Montgomery Martin, 216,663 lbs., and the exports of Arrow root were :—in 1830, 18,174 lbs., and in 1836, 76,699 lbs. The exports from that island of late years being—

	Tons.	Value.		Tons.	Value.
1857	45	£6,288	1860	40¾	£4,134
1858	46	5,451	1861	49¼	4,293
1859	21	2,853	1862	19	1,713

The exports from Jamaica were :—

	lbs.	Value.
1860	483,683	£10,794
1861	35,361	
1862	no return.	

and the exports from Natal, in South Africa, as follows :—

	Cwt.	Value.
1860	3,679	£6,680
1861	2,436	4,685
1862	983	1,547

Digitized by Google

Of arrow root prepared in the United Kingdom, we *exported*, in 1856, 21,243 lbs. the declared value of which was 714*l*. No returns of any exportation of any British arrow root have been made for some years; we may, therefore, infer that the manufactory has greatly declined.

ARSENIC, derived from the Greek ἀρσενικὸν, *masculine*, applied to orpiment on account of its potent powers. This metal occurs native, in veins, in crystalline rocks, and the older schists; it is found in the state of oxide, and also combined with sulphur under the improper name of *yellow* and *red arsenic*, or orpiment and realgar. Arsenic is associated with a great many metallic ores; but it is chiefly extracted in this country from those of tin, by roasting, in which case the white oxide of arsenic, or, more correctly, the arsenious acid, is obtained. On the Continent, arsenical cobalt is the chief source of arsenic.

The following are the principal ores of arsenic:—

Native Arsenic.—The most common form of native arsenic is reniform and stalactitic masses, often mammillated, and splitting off in thin successive layers like those of a shell. It possesses a somewhat metallic lustre, and a tin-white colour and streak, which soon tarnishes to a dark grey. Its specific gravity is 5·93. Before the blowpipe it gives out an alliaceous odour, and volatilises in white fumes. It is found in the silver mines of Freiberg, Annaberg, Marienburg, and Schneeberg, also Joachimsthal in Bohemia, Andreasberg in the Hartz, Kopnip in Transylvania, Orawitza in the Bannat, Kongsberg in Norway, Zimeoff in Siberia, in Alsace, and, according to Dana, at Haverhill, N. H. in the United States.

Arsenical Antimony. This mineral occurs at Allemont; also at Przibram in Bohemia, where it occurs in metallic veins associated with blende, antimony, and spathic iron; at Schladming in Styria; and Andreasberg in the Hartz. Its composition is:—Arsenic, 63·62; antimony, 36·38. When exposed to the action of the blowpipe, this mineral emits fumes of arsenic and antimony, and fuses to a metallic globule, which takes fire and burns away, leaving oxide of antimony on the charcoal.

White Arsenic or Arsenious Acid (*Arsenolite*), is often formed by the decomposition of other arsenical ores, and is composed of arsenic 65·76, and oxygen 24·24. It occurs either in minute radiating capillary crystals and crusts investing other substances, or in a stalactitic or botryoidal form. Before the blowpipe it volatilises in white fumes: in the inner flame it blackens and gives out an alliaceous odour; its specific gravity is 3·69. It is white, sometimes with a yellowish or reddish tinge, and has a silky or vitreous lustre. It possesses an astringent, sweetish taste.—H. W. B.

Realgar (anciently called *Sandaraca*), red orpiment, or ruby sulphur, is a *sulphide of arsenic*, having a composition: sulphur 29·91, arsenic 70·09. It occurs in Hungary, Saxony, and Switzerland.

Orpiment (a corruption of its Latin name, *auripigmentum*—golden paint), yellow sulphide of arsenic: its composition is, sulphur 39, arsenic 61. Burns with a blue flame on charcoal, and emits fumes of sulphur and arsenic. Dissolves in nitro-muriatic acid and ammonia.

Both realgar and orpiment are artificially prepared and used as pigments. See ORPIMENT, REALGAR.

ARSENIC is a brittle metal, of an iron-grey colour, with a good deal of brilliancy. It may be prepared by triturating arsenious acid, or the white arsenic of commerce, with black flux (charcoal and carbonate of potash), and subliming in a tube. If arsenical pyrites are ignited in close tubes, metallic arsenic sublimes, and sulphuret of iron remains. This metal, when exposed in the air, gradually absorbs oxygen, and falls into a grey powder (suboxide). This is sold on the Continent as *fly powder*.

To prepare arsenic on a larger scale, *mispickel*, or the other ores employed, are pounded; some pieces of old iron are mixed with the ore, to retain the combined sulphur, and the mixture placed in retorts between four and five feet in length, to which receivers are adapted. The retorts are moderately heated by a fire placed beneath them; the ores are decomposed, and metallic arsenic is sublimed and condensed in the receivers. The arsenic obtained in this way is purified by a second distillation with a little charcoal.

Arsenic is used in small quantities in the preparation of several alloys; it is employed in the manufacture of opal glass; also is much used in the manufacture of shot, to which it imparts a certain degree of hardness; and, by preventing the distortion of the falling drops of metal, and thus securing regular globules, the manufacture is greatly facilitated.

ARSENIC ACID. This acid was first produced on a large scale by M. G. Kopp. He employs nitric acid to convert arsenious acid by oxidation into arsenic acid, and

Digitized by Google

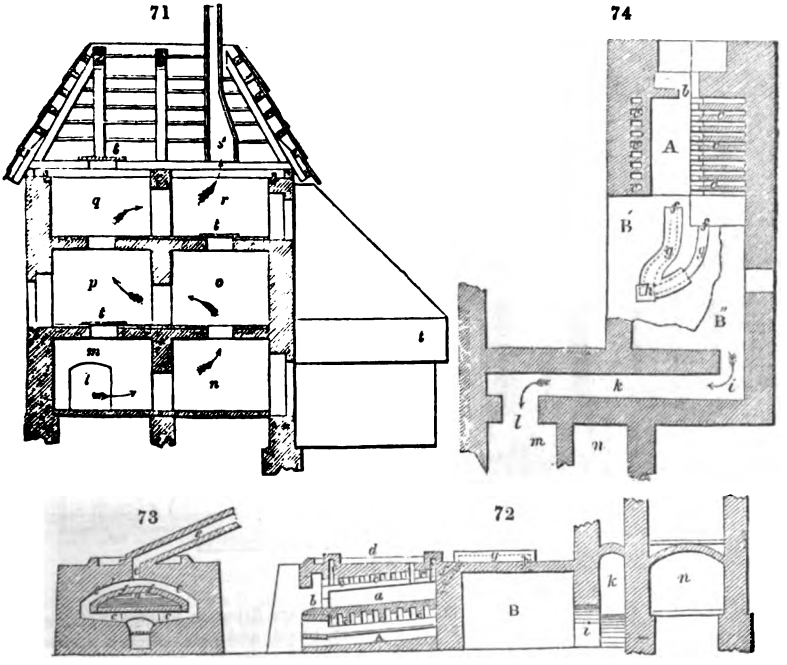
by passing the nitrous acid fumes evolved, together with air, over coke moistened with water, he recovers two-thirds or three-fourths of the nitric acid employed. The proportions he adopts are 303 kilogrammes (2 lbs. *and nearly a* ¼ lb. *avoirdupoise each*) of nitric acid of 1·35 sp. gr. to 400 kilogrammes of arsenious acid, and by adding the nitric acid gradually, the oxidizing action may be accomplished without the application of heat.

Arsenic acid is now almost universally employed in the manufacture of *Rosaniline*, and is therefore an article of great consumption. It is also largely used for the white discharge of Turkey Red.

M. Kopp has noticed, that without any injury to the general health, a natural tendency to stoutness was produced whilst working with arsenic acid. In the course of ten weeks, while engaged on experiments with Arsenic acid, M. Kopp himself increased in weight considerably more than twenty pounds, which he lost again when the experiments were concluded. The workpeople engaged in the manufacture of Rosaniline are similarly affected.

ARSENIOUS ACID, *White Arsenic, Flowers of Arsenic.*—This is the white arsenic of commerce, usually called Arsenic. It is obtained in this country from the arsenical ores of iron, tin, &c., and on the Continent from those of cobalt and nickel. It is prepared by heating the ores containing arsenic on the sole of a reverberatory furnace, through which a current of air, after passing through the grate, is allowed to play. The following ores are the more remarkable of this class,—the quantity of arsenic in 100 grains is given in each case.

Mispickel, or arsenical iron - - - - -	42·88
Lölingite, arsenical pyrites - - - - -	65·88
Kupfernickel, arsenical nickel - - - -	54·73
Rammelsbergite, white arsenical nickel - - -	72·64
Smaltine, tin-white cobalt - - - - -	74·22
Safflorite, arsenical cobalt - - - - -	70·37



In the roasting of tin ores, a considerable quantity of arsenious acid is collected in the flues leading from the furnaces in which this process is effected.

The extraction of white arsenic from the cobalt ores is performed at Altenberg and

Digitized by Google

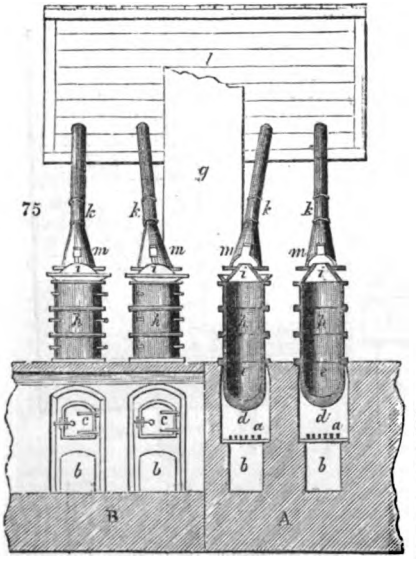
Reichenstein, in Silesia, with an apparatus excellently contrived to protect the health of the smelters from the vapours of this metallic sublimate.

Figs. 71 to 74 (p. 195) represent the arsenical furnaces at Altenberg. *Fig.* 71 is a vertical section of the poison tower; *fig.* 72 a longitudinal section of the subliming furnace A, with the adjoining vault B, and the poison tower in part at *n*; *fig.* 73, the transverse section of the furnace A, of *fig.* 72; *fig.* 74 ground plan of the furnace A, where the left half shows the part above, and the right the part below the muffle or oblong retorts; B′ is the upper view, B″ the ground plan of the vault B, of *fig.* 72; *m*, *n*, the base of the poison tower. In the several figures the same letters denote the same objects; *a* is the muffle; *b* is its mouth for turning over the arsenical schlich, or ground ore; *c*, *c*, *c*, fire draughts or flues; *d*, an aperture for charging the muffle with fresh schlich; *e*, the smoke chimney; *f*, two channels or flues for the ascent of the arsenious fumes, which proceed to other two flues *g*, and then terminate both in *h*, which conducts the fumes into the vault B. They issue, by the door, *i*, into the conduit *k*, thence by *l* into the spaces *m*, *n*, *o*, *p*, *q*, *r*, of the tower. The incondensable gases escape by the chimney, *s*. The cover *t* is removed after completion of the process, in order to push down the precipitate into the lower compartments.

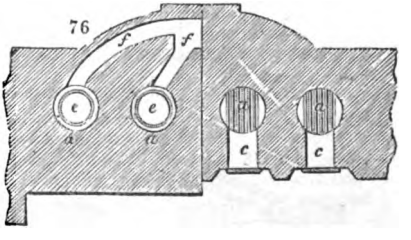
The arsenious schlichs, to the amount of 9 or 10 cwt. for one operation (1 *roast-post*, or roasting round), are spread 2 or 3 inches thick upon the bottom of the muffle, heated with a brisk fire to redness, then with a gentler heat, in order to oxidise completely, before subliming, the arsenical ore. With this view the air must have free entrance, and the front aperture of the muffle must be left quite open. After 11 or 12 hours, the calcined materials are raked out by the mouth of the muffle, and fresh ones are introduced by the openings indicated above, which are closed during the sublimation.

The arsenious acid found in these passages is not marketable till it be resublimed in large iron pots, surmounted with a series of sheet-iron drums or cast-iron cylinders, upon the sides of which the arsenic is condensed in its compact glassy form. The top cylinder is furnished with a pipe which terminates in a condensing chamber.

Figs. 75, 76, represent the arsenic refining furnaces at Reichenstein. *Fig.* 75 shows at A, a vertical section of the furnace, the kettle, and the surmounting drums or cylinders; over B it is seen in elevation; *fig.* 76 is a ground plan of the four fire-places. *a* is the grate; *b*, the ash-pit; *c*, the openings for firing; *d*, the fire-place; *e*, iron pots or kettles which are charged with the arsenious powder; *f*, the fire flues proceeding to the common chimney *g*; *h*, iron cylinders; *i*, caps; *k*, pipes leading to the poison-vent *l*; *m*, openings in the pipes for introducing the probing wires.



The conduct of the process is as follows:—The pot is filled nearly to



its brim with 3½ cwt. of the arsenic meal; the cylinders are fitted on by means of their handles, and luted together with a mixture of loam, blood, and hair; then is applied first a gentle, and after half an hour, a strong fire, whereby the arsenic is raised partly in the form of a white dust, and partly in crystals; which, by the continuance of the heat, fuse together into a homogeneous mass. If the fire be too feeble, only a sublimate is obtained; but if too violent, much of the arsenic is volatilised into the

Digitized by Google

pipes. The workmen judge by the heat of the cylinders whether the operation be going on well or not. After 12 hours the furnace is allowed to cool, provided the probe wires show that the sublimation is over. The cylinders are then lifted off, and the arsenious glass is detached from their inner surface. According to the quality of the poison-flour, it yields from $\frac{3}{4}$ths to $\frac{7}{8}$ths of its weight of the glass or enamel. Should any dark particles of metallic arsenic be intermixed with the glass, a fresh sublimation must be had recourse to.

In these operations, if any sulphur is present it is converted into sulphurous acid, which escapes through the chimney, while the arsenious acid is condensed in proper chambers, placed in the flues to receive it. Freshly prepared arsenious acid is a perfectly transparent solid mass; but by exposure it becomes transformed into an opaque body resembling porcelain.

White arsenic is extensively used in the preparation of various pigments, as the *bisulphide*, or realgar, the *tersulphide*, or orpiment, and also in the mineral greens used by paper-stainers. It has been stated that papers stained with the arsenical greens are injurious to health. Very much has been said on this subject; but the following remarks by Mr. Alfred Fletcher appear to settle the question:—"Now, it is stated that in a medical work an instance is noted in which injury has been received by those living in rooms decorated with these colours: surely, were the proximity of such materials injurious, it would not be necessary to search in recondite books for the registry of isolated cases. The fact of the large extent to which such materials have always been employed is a sufficient proof that there is no danger attending their use; moreover, workmen who have been daily employed for many years in manufacturing large quantities of these colours, under the necessity of constantly handling them, are in the regular enjoyment of perfect health, though exposed also to the general influences of a chemical factory. Let blame be laid at the right door, and let the public be assured that it is not the looking at cheerful walls, the fingering of brightly ornamented books, nor the wearing of tastefully coloured clothing, that will hurt them, but the dwelling in ill-ventilated rooms."

Arsenite of Copper.—Scheele's green is a combination of arsenious acid with oxide of copper, or an arsenite of copper, and is described under that metal.

Arseniate of Potash is prepared, in the small way, by exposing to a moderate heat, in a crucible, a mixture of equal parts of white arsenic and nitre in powder. After fusion the crucible is to be cooled; the contents being dissolved in hot water, and the solution filtered, will afford regular crystals on cooling. According to M. Berzelius, they are composed of arsenic acid, 63·87; potash, 26·16; and water, 9·97. It is an acidulous salt, and is hence usually called the binarseniate, to denote that its composition is 2 atoms of arsenic acid and 1 of potash. This article is prepared upon the great scale, in Saxony, by melting nitre and arsenious acid together in a cylinder of cast iron. A neutral arseniate also is readily formed by saturating the excess of acid in the above salt with potash; it does not crystallise. The acid arseniate is occasionally used in calico printing, for preventing certain points of the cotton cloth from taking on the mordant; with which view it is mixed up with gum water and pipe clay into a paste, which is applied to such places with a block.

ARSENIC, POISONING BY.—This poison is so commonly the cause of death, by accident and by design, that it is important to name an antidote which has been employed with very great success.

This is the *hydrated peroxide of iron*. This preparation has no action on the system, and it may therefore be administered as largely and as quickly as possible. The following statement will render the action of this hydrated salt intelligible. When hydrated peroxide of iron is mixed in a thin paste with the solution of arsenious acid, this disappears, being changed into arsenic acid (a far less active oxide), and the iron into protoxide $2Fe^2O^2$ and AsO^5, producing $4FeO + As^2O^5$. The hydrated peroxide of iron may be made in a few minutes by adding carbonate of soda to any salt of the red oxide of iron (permuriate, muriate, acetate, &c.). It need not be washed, as the liquor contains only a salt of soda, which would be, if not beneficial, certainly not injurious.—*Kane.*

Detection of Arsenic in Cases of Poisoning.

Arsenious acid, which is almost always the form in which the arsenic has entered the system, possesses the power of preventing the putrefaction of animal substances; and hence the bodies of persons that have been poisoned by it do not readily putrefy. The arsenious acid combines with the fatty and albuminous tissues to form solid compounds, which are not susceptible of alteration under ordinary circumstances. It hence has frequently occurred that the bodies of persons poisoned by arsenic have been found, long after death, scarcely at all decomposed; and even where the

Digitized by Google

general mass of the body had completely disappeared, the stomach and intestines had remained preserved by the arsenious acid which had combined with them, and by its detection the crimes committed many years before have been brought to light and punished. — *Kane.*

The presence of arsenic may be determined by one of the following methods: —

1. Portions of the contents of the stomach or bowels being gently heated in a glass tube, open at both ends, the arsenic, if in any quantity, will be sublimed, and collected as minute brilliant octahedrons.

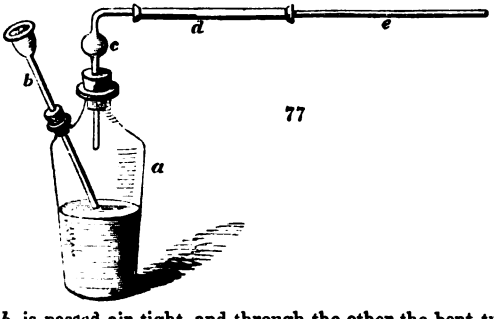
2. Or by the presence of organic matter; if the ignition is effected in a tube closed at one end, metallic arsenic sublimes, forming a steel-grey coat, and emitting a strong smell of garlic.

3. *Ammonia Nitrate of Silver* produces a canary-yellow precipitate from a solution of arsenious acid (*arsenite of silver*). The phosphate of soda produces a yellow precipitate of tribasic phosphate of silver, which exactly resembles the arsenite. The phosphate is, however, the more soluble in ammonia, and when heated gives no volatile product; while the arsenite is decomposed with white arsenic and oxygen, leaving metallic silver behind.

4. *Ammonia Sulphate of Copper* produces a fine apple-green precipitate, which is dissolved in an excess of either acid or ammonia. It is, however, uncertain, unless the precipitate be dried and reduced.

5. *The Reduction Test.*—Any portion of the suspected matter, being dried, is mixed with equal parts of cyanide of potassium and carbonate of potash, both dry. This mixture is to be introduced into a tube terminating in a bulb, to which heat is applied, when metallic arsenic sublimes.

6. *Marsh's Test.*—This is one of the most delicate and useful of tests for this poison, and when performed with due care there is little liability to error. The liquid contents of the stomach, or any solution obtained by boiling the contents, is freed as much as possible from animal matter by any of the well known methods for doing so. This fluid is then rendered moderately acid by sulphuric acid, and introduced into a bottle properly arranged.



77

Fig. 77 is the best form for Marsh's apparatus:— *a* is a bottle capable of holding half, or, at most, a pint. Both necks are fitted with new perforated corks, which must be perfectly tight. Through one of these the funnel tube, *b*, is passed air-tight, and through the other the bent tube, *c*, which is expanded at *e* into a bulb about an inch in diameter. This bulb serves to collect the particles of liquid which are thrown up from the contents of the bottle, and which drop again into the latter from the end of the tube. The other end of the tube is connected, by means of a cork, with tube *d*, about six inches long, which is filled with fused chloride of calcium, free from powder, destined to retain the moisture. In the opposite end of the tube *d* is fixed, air-tight, another tube, *e*, made of glass free from lead, 12 inches long, and, at most, $\frac{1}{9}$th of an inch in internal diameter. It must be observed that the funnel tube *d* is indispensably necessary to introduce the fluid to the pieces of perfectly pure metallic zinc already placed in the bottle. Hydrogen gas is at once formed, and if arsenic is present, in even the smallest quantity, it combines with the hydrogen, and (*gaseous arseniuretted hydrogen*) escapes. If the gas as it issues from the jet is set on fire, no product but water is generated if the hydrogen is pure; and by holding against the flame a cold white porcelain basin, or piece of glass, or of mica, no steam is produced, and a dew is formed upon the cold surface. If arsenic be present, a deposit is obtained, which, according to the part of the flame in which the substance to receive it is placed, will be either a brown stain of metallic arsenic, or a white one of arsenious acid. If the quantity of arsenic is too small to be detected in this way, it will be well to ignite the horizontal part of the tube. All the arseniuretted hydrogen will, in passing that point, become decomposed, and deposit its arsenic. The heat will drive this forward, and a little beyond the heated portion metallic arsenic will be condensed. Several precautions are necessary to be observed; but for the details of those we must refer to works especially directed to the consideration of this subject. One source of error must, however, be alluded to. A compound of antimony and hydrogen is formed under similar circumstances; and this

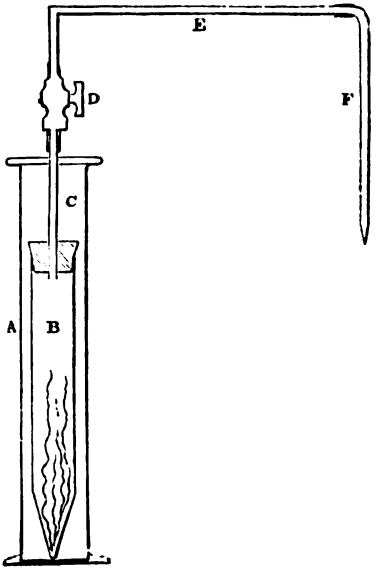
Digitized by Google

gas in many respects resembles the compound of arsenic and hydrogen. If the stain formed by the flame is arsenic, it will dissolve, when heated, in a drop or two of sulpho-hydride of ammonia, and a lemon-yellow spot is left; if antimony is present, it leaves a yellow stain.— *Wöhler.*

If a drop of bromine is placed on a saucer, and a capsule containing arsenical spots inverted over it, the spots take a very bright lemon-yellow tinge in a short time. Antimonial spots, under the same circumstances, are acted on much more rapidly (in about five seconds at a temperature of 52° F.), and assume an orange shade. Both become colourless if exposed to the air, and are again restored if treated with a strong solution of sulphuretted hydrogen. The secondary yellow of the arsenical spots, as observed by Lassaigne, disappears on the addition of ammonia, whilst that of antimonial spots remains untouched. A concentrated solution of iodate of potash turns arsenical spots of a cinnamon-red and dissolves them almost immediately. On antimonial spots it has no visible action within three or four hours. Solutions of the hypochlorites (chlorides) of soda and lime and chlorine water dissolve arsenical spots instantaneously, leaving those of antimony. A concentrated solution of the chlorate of potash gradually acts upon arsenical spots, but not upon those of antimony. The nitroprusside of potassium, on the other hand, slowly dissolves antimony, producing no perceptible effect upon arsenic. The statement of Bischoff, that arsenical spots were soluble, antimonial insolnble, in a solution of the chloride of sodium, could not be verified, as, after repeated trials, it was found to leave both not perceptibly affected. The chlorine of barium, the hypochlorate and the sulphite of ammonia, afforded likewise no distinguishing action. The nitrate of ammonia dissolves arsenical more rapidly than antimonial stains. Of these reactions the most decisive are those of iodate of potash, hypochlorites of soda and lime, and fresh chlorine water.

It is well known that fluids mixed with glutinous matter are very liable to froth up when hydrogen is disengaged in them, from the mutual action of zinc and a dilute acid; and that the froth obstructs the due performance of the experiment of Marsh. A committee appointed by the Prussian Government contrived an ingenious modification of Marsh's apparatus, the annexed form (*fig.* 78) representing an ingenious simplification of it by Dr. Ure:—A, is a narrow glass cylinder, open at top, about 10 inches high, and 1¼ or 1½ inch diameter inside; B is a glass tube, about 1 inch diameter outside, drawn to a point at bottom, and shut with a cork at top. Through the centre of this cork the small tube C passes down air-tight, and is furnished at top with a stopcock, into which the bent small tube of glass (without lead) E is cemented. The bent tube F is joined to the end of E with a collar of caoutchouc, or a perforated cork, which will be found more convenient.

78



The manner of using this apparatus is as follows:—Introduce a few oblong slips of zinc, free from arsenic, into B, and then insert its air-tight cork with the attached tubes. Having opened the stopcock, pour into A as much of the suspected liquid, acidulated with dilute hydrochloric or sulphuric acid (each pure) as will rise to the top of the cork, after B is full, and immediately shut the stopcock. The generated hydrogen will force down the liquid out of the lower orifice of B into A, and raise the level of it above the cork. The extremity of the tube F being dipped beneath the surface of a weak solution of nitrate of silver, and a spirit-flame being placed a little to the left of the letter E, the stopcock is then to be slightly opened, so that the gas which now fills the tube B may escape so slowly as to pass off in separate small bubbles through the silver solution. By this means the whole of the arsenic contained in the arseniuretted hydrogen will be deposited either in the metallic state upon the inside of the tube E, or with the silver into the characteristic black powder. The first charge of gas in B being expended, the stopcock is to be shut till the liquid be again expelled from it by a fresh disengagement of hydrogen.

Digitized by Google

The ring of metallic arsenic deposited beyond E may be chased onwards by placing a second flame under it, and thereby formed into an oblong brilliant steel-like mirror. It is evident that by the patient use of this apparatus the whole arsenic in any poisonous liquid may be collected, weighed, and subjected to every kind of chemical verification. If F be joined to E by means of a perforated cork, it may readily be turned about, and its taper point raised into a position such as when the hydrogen issuing from it is kindled, the flame may be made to play upon a surface of glass or porcelain, in order to produce the arsenical mirror.

7. *Reinsch's Test.* — Professor Reinsch has proposed an entirely new method of detecting arsenic, which consists in acidulating any suspected fluid with hydrochloric acid, heating in it a thin plate of bright copper, upon which the arsenic is deposited in the form of a thin metallic crust, and then separating the arsenic from the copper in the state of oxide by subjecting the copper to a low red heat in a glass tube. Organic fluids and solids suspected to contain arsenic, may be prepared for this purpose by boiling them for half an hour with a little hydrochloric acid; solid matters being cut into small shreds, water being added in sufficient quantity to let the ebullition go on quietly, and care being taken to continue the boiling until the solids are either dissolved, as generally happens, or are reduced to a state of minute division.

The method of Reinsch is exceedingly delicate, for it is adequate to detect a 250,000th part of arsenic in a fluid. It is also perfect in another respect: it does not leave any arsenic in the subject of analysis; none, at least, which can be detected by any other means, even by the most delicate process yet proposed, that of Mr. Marsh.

Cut the copper on which the arsenic is deposited into small chips, so that they may be easily packed in the bottom of a small glass tube, and apply a low red heat. A white crystalline powder sublimes; and if this be examined in the sunshine, or with a candle near it, a magnifier of four or five powers will enable the observer to distinguish the equilateral triangles composing the facets of the octahedral crystals, which are formed by arsenious acid when it sublimes. Sometimes the three equal angles, composing a corner of the octahedron, may be seen by turning the glass in various directions. If triangular facets cannot be distinguished, owing to the minuteness of the crystals, then shake out the copper chips, close the open end of the tube with the finger, and heat the sublimed powder over a very minute spirit-lamp flame, chasing it up and down the tube till crystals of adequate size are formed. Next boil a little distilled water in the tube over the part where the crystalline powder is collected; and when the solution is cold, divide it into three parts, to be tested with ammoniacal nitrate of silver, ammoniacal sulphate of copper, and sulphuretted hydrogen, either in the state of gas or dissolved in water.

8. *Fleitmann's Test.* — If a solution containing arsenic be mixed with a large excess of concentrated solution of potassa, and boiled with fragments of granulated zinc, arseniuretted hydrogen is evolved, and may be easily reorganised by allowing it to pass on to a piece of filter paper spotted over with solution of nitrate of silver. These spots assume a purplish-black colour, even when a small quantity of arsenic is present. This experiment may be performed in a small flask, furnished with a perforated cork carrying a piece of glass tube of about ¼ inch diameter. It will be observed that this test serves to distinguish arsenic from antimony.

The following remarks on the *Toxicological Discovery of Arsenic* deserve attention:—

This active and easily administered poison is fortunately one of those most easily and certainly discovered; but the processes require great precaution to prevent mistaken inferences: if due care is taken, arsenic can be found after any lapse of time, as well as after the most complete putrefaction of the animal remains. The longest time after which it has been discovered by myself is eight years, which was the case of an infant; nothing but the bones of the skeleton remained, the coffin was full of earth, and large roots of a tree had grown through it. The metal was obtained from the bones, and in the earth immediately below where the stomach had existed. Many cases have occurred in my experience, where one, two, three, four, and five years have elapsed; in one case, after fourteen months, where the body of a boy had been floating in a coffin full of water. The poison is given in one of three states, white arsenious acid, yellow sulphuret ("orpiment"), or "realgar," red sulphuret of arsenic; and it is worthy of notice that putrefaction will turn either white or red into yellow, but will never turn yellow into either white or red; this is owing to the hydrosulphuret of ammonia disengaged during decomposition.

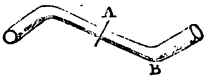
Modern toxicologists have abandoned all the old processes for the detection of this poison, and have adopted one of two, which have been found more expeditious, as well as more certain. The first was proposed by Marsh, of Woolwich: it is founded upon the principle that nascent hydrogen will absorb and carry off any arsenic which may

Digitized by Google

be present, as arseniuretted hydrogen; but as I prefer the principle first proposed by Reinsch, and have always acted upon it, I shall confine my description to the processes founded upon it. The principle is this: arsenic mixed or combined with any organic matter will, if boiled with pure hydrochloric acid and metallic copper, be deposited upon the copper; but as this depositing property is also possessed by mercury, antimony, bismuth, lead, and tellurium, subsequent operations are required to discriminate between the deposits. I take pieces of copper wire, about No. 13 size, and 2½ inches long; these I hammer on a polished plane with a polished hammer, for half their length (*fig.* 79), and having brought the suspected matters to a state of dryness, and boiled the copper blade in the pure hydrochloric acid, to prove that it contains no metal capable of depositing, I introduce a portion of the suspected matter and continue the boiling; if the copper becomes now either steel-grey, blue, or black, I remove it, and wash it free of grease in another vessel in which there is hot diluted hydrochloric acid; I now dry it, and, with a scraper with a fine edge, take off the deposit with some of the adhering copper, and repeat the boiling, washing, and scraping, so as to have four or five specimens on copper; one of these is sealed up hermetically in a tube for future production. I now take a piece of glass tube, and having heated it in the middle, draw it out, as in *fig.* 80, dividing it at A, each section being about 2 inches long, the wide orifices being about $\frac{1}{10}$ths of an inch in diameter, and ½ an inch long, the capillary part $\frac{1}{8}$th of an inch in diameter and 1½ inch long; now, by putting one portion of the scrapings into one of the tubes at B, and holding it upwards over a very small flame, so that the volatile products may slowly ascend into the narrow portion of the tube, we prove the nature of the deposit: if mercury, it condenses in minute white shining globules; if lead or bismuth, it does not rise but melts into a yellowish glass, which adheres to the copper; if tellurium, it would fall as a white amorphous powder; if antimony, it would not rise at that low temperature; but arsenious acid condenses as minute octahedral crystals, looking with the microscope like very transparent grains of sand. I make three such sublimates, one of which is sealed up like the arsenic for future production. I now cut the capillary part of another of the tubes in pieces, and boil it in a few drops (say 10) of distilled water, and when cold drop three or four drops on a plate of white porcelain, and with a glass rod drop one drop of ammoniacal sulphate of copper in it: and now to make the colours from this and the next test more conspicuous, I keep a chalk stone, planed and cleaned, in readiness, and placing on it a bit of clean white filtering paper, I conduct the drops of copper test upon the paper, which permits the excess of copper solution to pass through into the chalk, but retains the smallest proportion of Scheele's green; the other few drops of the solution are treated the same way with the ammoniacal nitrate of silver. When I get the yellow precipitate of arsenite of silver, the papers, with these two spots, are now dried and sealed up in a tube as before, and that with the silver must be kept in the dark, or it will become black. I have still one of the tubes with the arsenical sublimate remaining; through this I direct a stream of hydrosulphuric acid gas for a few seconds, which converts the sublimate into yellow orpiment. I have now all five tests: the metal, the acid, arsenite of copper, arsenite of silver, and yellow sulphuret; and the $\frac{1}{100000}$th of a grain of arsenic is sufficient in adroit hands to produce the whole; but all five must be present, or there is no positive proof, for many matters will cause a darkness of the copper in the absence of arsenic,—sulphurets even from putrefaction;—but there is no sublimate in the second operation, because the sulphur burns into sulphurous acid and passes off upwards. Corn, grasses, and earth slightly darken it from some unknown cause, but produce no sublimate; so, if the solution of suspected arsenious acid is tested with the copper test while hot, it will produce a greenish deposit of oxide of copper, through the heat dissipating a little ammonia, or if the copper blade has not been deprived of grease by the diluted hydrochloric acid, the sublimed acid from the grease will precipitate copper from that test; but as much of the sulphuric acid of commerce, and nearly all such hydrochloric acid and some commercial zinc contains arsenic, nothing can excuse a toxicologist who attempts to try for arsenic if he has not previously experimented with all his reagents before he introduces the suspected matters. I should also mention that this metal is to be found in all parts of the body, but longest, and in greatest quantity, in the liver, where it is frequently found many days after it has disappeared from the intestines. — *W. Herapath.*

79

80



Arsenious acid of commerce is frequently adulterated with chalk or plaster of Paris. These impurities are very easily detected, and their proportions estimated. Arsenious acid is entirely volatilised by heat, consequently it is sufficient to expose a weighed quantity of the substance to a temperature of about 400° F. in a capsule or

Digitized by Google

crucible. The whole of the arsenic will pass off in fumes, while the impurities will be left behind as a fixed residuum, which can, upon cooling, be weighed.

The mines of Cornwall and Devonshire produced in 1863, 1,444 tons of Arsenic, of the value of £1,200, and in 1864, 1,858 tons, valued at £1,393 10*s.*

Our *Imports* and *Exports* of ARSENIC were as follows:—

1864 - - - - -	84 „	19,660 „

ARTESIAN WELLS. Under this name is designated a cylindrical perforation, bored vertically down through one or more of the strata of the earth, till it passes into a porous gravel bed containing water, placed under such incumbent pressure as to make the fluid rise through the perforation, either to the surface or to a height convenient for the operation of a pump. In the first case, these wells are called spouting or overflowing. These wells derive their name from Artois, one of the provinces of France, in the *département du pas de Calais*, where the practice of employing them was revived. They have been used for a long period in the East and in Italy.

M. Lefebvre, "Comptes Rendus de l'Acad. des Sciences, 1838," describes several very ancient Artesian wells, which were discovered by M. Ayme in the Oasis of Thebes. These appear to have been sunk through 80 feet of clay and marls, and then through 300 feet of limestone. M. Ayme states that in the Lybian desert, where there are no rivers or springs, and upon which rain never falls, formerly a large population was supplied with water by Artesian wells, several of which have been cleared out and restored by this French engineer with perfect success. The "Wells of Solomon" in the plains of Tyre are supposed to be of this description. There are now many such wells in London and its neighbourhood, perforated through the immensely thick bed of the London clay, and even through some portions of the subjacent chalk.

The formation of Artesian wells depends on two things, essentially distinct from each other: 1, On an acquaintance with the physical constitution of the rocks forming the district of any country and their relative situations, in the locality where the water supply is required, and in those distant spots from which the water is expected to be derived; and, 2, On the skilful direction of the processes by which we can reach the water level, and of those by which we can promote its ascent in the tube.

The operations employed for penetrating the soil are entirely similar to those daily practised by the miner; but the well excavator must resort to peculiar expedients to prevent the purer water, which comes from deep strata, mingling with the cruder waters of the alluvial beds near the surface of the ground, as also to prevent the small perforation getting eventually filled with rubbish.

The cause of overflowing wells has been ascribed to a variety of circumstances. But, as it is now generally admitted that the numerous springs which issue from the ground proceed from the infiltration of the waters progressively condensed in rain, dew, snow, &c. upon the surface of our globe, the theory of these interior streamlets becomes by no means intricate; being analogous to that of syphons and water jets, as expounded in treatises of physics. The waters are diffused, after condensation, upon the surface of the soil, and percolate downwards, through the various pores and fissures of the geological strata, to be again united subterraneously in veins, rills, streamlets, or expanded films, of greater or less magnitude or regularity. The beds traversed by numerous disjunctions will give occasion to numerous interior currents in all directions, which cannot be recovered and brought to the day; but when the ground is composed of strata of sand, or gravel very permeable to water, separated by other strata nearly impervious to it, reservoirs are formed to our hand, from which an abundant supply of water may be spontaneously raised. In this case, as soon as the upper stratum is perforated, the waters may rise, in consequence of the hydrostatic pressure upon the lower strata, and even overflow the surface in a constant stream, provided the level from which they proceed be proportionally higher.

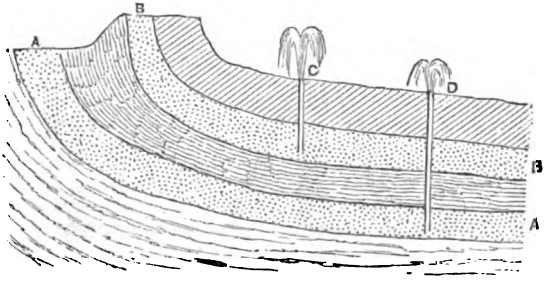
The sheets of water occur principally at the separation of two contiguous formations; and, if the succession of the geological strata be considered, this distribution of the water will be seen to be its necessary consequence. In fact, the lower beds are frequently composed of compact sandstone or limestone, and the upper beds of clay. In level countries, the formations being almost always in horizontal beds, the waters which feed the Artesian wells must come from districts somewhat remote, where the strata are more elevated, as towards the second and transition rocks. The copious streams condensed upon the sides of these colder lands may be therefore regarded as the proper reservoirs of our wells.

Fig. 81 represents the manner in which the condensed water of the heavens may be supposed to distribute itself upon a portion of the surface of our globe. Here we have a geological section, showing the succession of the several formations.

Digitized by Google

The figure is supposed to represent two beds, A, B, more porous and consequently more absorbent than the rocks with which they are interstratified. The dews condensed and rains falling upon the distant hills pass rapidly by the outcrops of these strata to the lower levels, until the whole mass becomes thoroughly saturated with water. Supposing two such beds as are represented in the section to exist fully charged with water, it is evident that if we sank "bore-holes" through the rocks down to them, as represented at C, D, the water would rise through those wells, and jet out to such a height above the surface as is due to the height of the hills from which the water has been obtained. The fountain derived from B would necessarily flow as much higher than that derived from the bed A, as is the height of B above A.

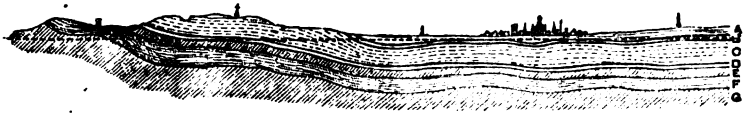
81



The annexed section (*fig.* 82) is an actual one of the country from Sussex to Bedfordshire, as given by Mr. Prestwich. In this drawing the lower stratum is the *Kimmeridge and Weald clay*, G, which is impermeable; upon this rests the *lower greensand*, F, which is permeable, and probably highly charged with water; the *gault*, E, above, which is impermeable; then we have the *upper greensand*, D, *chalk*, C, *sands and mottled clay*, B, *London clay* and *Bagshot sands*, A, all of which are more or less permeable, except the *London clay*.

The line of Trinity high-water mark crosses the section, and it will be understood, confining our attention to the lower greensand only, that if a well is sunk from London through the upper strata to the greensand, that the water will rise through that open-

82



ing, and spout out above the surface, so long as the water in the greensand basin is supported at a height above the Trinity mark.

For exact information of the details of constructing Artesian wells, the reader is referred to "Traité sur les Puits Artésiens," by M. Garnier, and to "Considérations Géologiques et Physiques sur la Théorie des Puits forés, ou Fontaines Artésiennes," by M. le Vicomte Hericart de Thury, and to "Rudimentary Treatise on Well-Digging, Boring," &c., by Mr. J. G. Swindell. The following description given by the late Dr. Ure is valuable, and is consequently preserved, with very slight alterations, although we consider it scarcely in place in a dictionary which does not profess to deal with practical engineering.

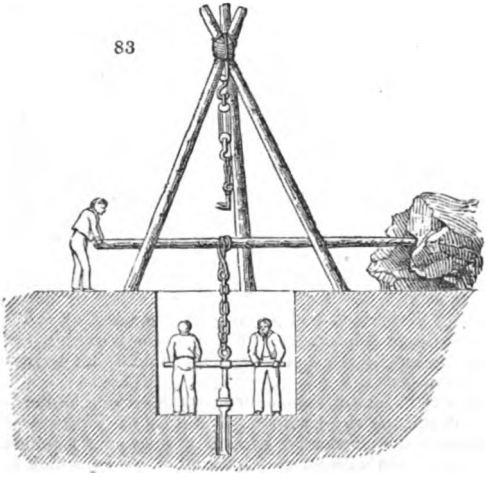
The situation of the intended well being determined upon, a circular hole is generally dug in the ground, about 6 or 8 feet deep, and 5 or 6 feet wide. In the centre of this hole the boring is carried on by two workmen below, assisted by a labourer above, as shown in *fig.* 83.

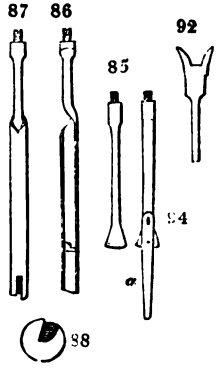
The handle (*fig.* 84) having a female screw in the bottom of its iron shank, with a wooden bar or rail passing through the socket of the shank, and a ring at top, is the general agent to which all the boring implements are to be attached. A chisel (*fig.* 85) is first employed, and connected to this handle by its screw at top. If the ground is tolerably soft, the weight of the two workmen bearing upon the crossbar, and occasionally forcing it round, will soon cause the chisel to penetrate; but if the ground is hard or strong, the workmen strike the chisel down with repeated blows, so as to peck their way, often changing their situation by walking round, which breaks the stones, or other hard substances, that may happen to obstruct its progress.

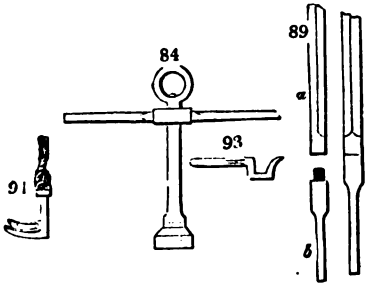
The labour is very considerably reduced by means of an elastic wooden pole, placed horizontally over the well, from which a chain is brought down, and attached to the ring of the handle. This pole is usually made fast at one end, as a fulcrum, by being set into a heap of heavy loose stones; at the other end the labourer above gives it a

Digitized by Google

slight up and down vibrating motion, corresponding to the beating motion of the workmen below, by which means the elasticity of the pole in rising lifts the handle







and pecker, and thereby very considerably diminishes the labour of the workmen. See *fig.* 83.

When the hole has been thus opened by a chisel, as far as its length will permit, the chisel is withdrawn, and a sort of a cylindrical auger (*fig.* 86) attached to the handle (*fig.* 84), for the purpose of drawing up the dirt or broken stones which have been disturbed by the chisel. A section of this auger is shown in *fig.* 87, by which the internal valve will be seen. The auger being introduced into the hole and turned round by the workman, the dirt or broken stones will pass through the aperture at bottom (shown at *fig.* 88), and fill the cylinder, which is then drawn up and discharged at the top of the auger, the valve preventing its escape at bottom.

In order to penetrate deeper into the ground, an iron rod, as *a* (*fig.* 89) is now to be attached to the chisel (*fig.* 85) by screwing on to its upper end, and the rod is also fastened to the handle (*fig.* 84) by screwing into its socket. The chisel, having thus become lengthened by the addition of the rod, is again introduced into the hole; and the operation of pecking, or forcing it down, is carried on by the workmen as before. When the ground has been thus perforated as far as the chisel and its rod will reach, they must be withdrawn in order again to introduce the auger (*fig.* 86) to collect and bring up the rubbish; which is done by attaching it to the iron rod in place of the chisel. Thus as the hole becomes deepened, other lengths of iron rods are added, by connecting them together, as *a b* are in *fig.* 90. The necessity of frequently withdrawing the rods from the holes, in order to collect the mud, stones, or rubbish, and the great friction produced by the rubbing of the tools against its sides, as well as the lengths of rods augmenting in the progress of the operation, sometimes to the extent of several hundred feet, render it extremely inconvenient, if not impossible, to raise them by hand. A tripedal standard is therefore generally constructed by three scaffolding poles tied together over the hole (as shown *fig.* 83), from the centre of which a wheel and axle, or a pair of pulley-blocks, is suspended for the purpose of hauling up the rods, and from which hangs the fork (*fig.* 91.) This fork is to be brought down under the shoulder, near the top of each rod, and made fast to it by passing a pin through two little holes in the claws. The rods are thus drawn up, about seven feet at a time, which is the usual distance between each joint, and at every haul a fork (*fig.* 92) is laid horizontally over the hole, with the shoulders of the lower rod resting between its claws, by which means the rods are prevented from sinking down into the hole again, while the upper length is unscrewed and removed. In attaching and detaching these lengths

Digitized by Google

of rod, a wrench (*fig.* 93) is employed by which they are turned round, and the screws forced up to their firm bearing.

The boring is sometimes performed for the first sixty or a hundred feet by a chisel of 2¼ inches wide, and cleared out by a gouge of 2¼ diameter, and then the hole is widened by a tool such as is shown at *fig.* 94. This is merely a chisel (as *fig.* 85) four inches wide, but with a guide, *a*, put on at its lower part, for the purpose of keeping it in a perpendicular direction; the lower part is not intended to peck, but to pass down the hole previously made, while the sides of the chisel operate in enlarging the hole to four inches. The process, however, is generally performed at one operation, by a chisel of four inches wide (as *fig.* 85), and a gouge of three inches and three-quarters (as *fig.* 86).

It is obvious, that placing and displacing the lengths of rod, which is done every time that the auger is required to be introduced or withdrawn, must of itself be extremely troublesome, independent of the labour of boring, but yet the operation proceeds, when no unpropitious circumstances attend it, with a facility almost incredible. Sometimes, however, rocks which require great labour to penetrate intercept the way; but this is always affected by pecking, which slowly pulverises the stone. The most unpleasant circumstance attendant upon this business is the occasional breaking of a rod in the hole, which sometimes creates a delay of many days, and an incalculable labour in drawing up the lower portion.

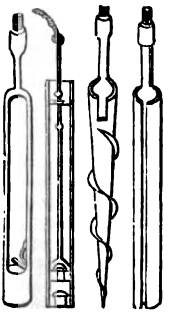
When the water is obtained in such quantities and of such quality as may be required, the hole is dressed or finished by passing down it a diamond chisel, funnel-mouthed, with a triangular bit in its centre; this makes the sides smooth previous to putting in the pipe. This chisel is attached to rods and to the handle, as before described; and, in its descent the workmen continually walk round, by which the hole is made smooth and cylindrical.

In order to keep the water which we desire to obtain pure, and uncontaminated with mineral springs, or by surface drainage contaminated with organic matter, which would pass into the hole through the permeable strata near the surface, the hole is cased, for a considerable depth, with a metallic pipe, about a quarter of an inch smaller than the bore. This is generally made of tin (though sometimes of copper or lead), in convenient lengths; and, as each length is let down, it is held by a shoulder resting in a fork, while another length is soldered to it; by which means a continuous pipe is carried through the bore, as far as may be found necessary, to exclude land springs, and to prevent loose earth or sand from falling in and choking the aperture.

It sometimes happens, in sinking Artesian wells, that one or more lines of water may be tapped which it is desirable to avoid. To prevent the mixture of good and bad water, the diameter of the boring is increased from the surface to the bed, or the instertices between the strata, and a hollow cylinder is passed down through its centre to the continuation of the boring beneath the line of bad water, in such a manner that it cannot mix with the good water coming from below. Thus the bad water, rising, ascends on the outside of the cylinder, while the good water rises within it.

Mr. John Good, of Tottenham, who has been extensively employed in boring the earth for water, obtained a patent, in August, 1823, for certain improved implements contrived by him to facilitate his useful labours; a description of which cannot fail to be interesting.

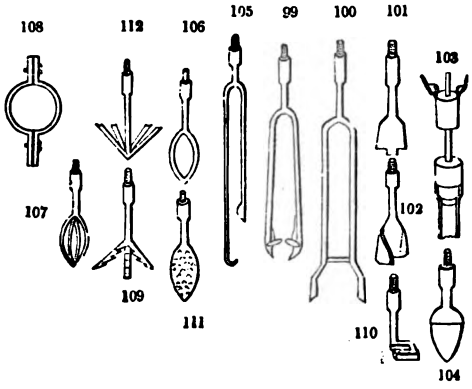
The figures annexed exhibit these ingenious tools; *fig.* 95 is an auger, to be connected by the screw-head to the length of rods by which the boring is carried on. This auger is for boring in soft clay or sand; it is cylindrical, and has a slit or opening from end to end, and a bit or cutting-piece at bottom. When the earth is loose or wet, an auger of the same form is to be employed, but the slit or opening reduced in width, or even without a slit or opening. A similar auger is used for cutting through chalk; but the point or bit at bottom should then project lower, and, for that purpose, some of these cylindrical augers are made with movable bits, to be attached by screws, which is extremely desirable in grinding them to cutting edges. *Fig.* 96 is a hollow conical auger, for boring loose sandy soils; it has a spiral cutting edge coiled round it, which, as it turns, causes the loose soil to ascend the inclined plane, and deposit itself in the hollow within. *Fig.* 97 is a hollow cylinder or tube, shown in section, with a foot-valve, and a bucket to be raised by a rod and cord attached at the top; this is a pumping tool for the purpose of getting up water and sand that would not rise by the auger. When this cylinder is lowered to the bottom of the bore, the bucket is lifted up by the rod and cord, and



Digitized by Google

descends again by its own gravity, having a valve in the bucket, opening upwards, like other lift-pumps, which, at every stroke, raises a quantity of water and sand in the cylinder equal to the stroke; the ascent and descent of the bucket being limited by a guide-piece at the top of the cylinder, and two small knobs upon the rod, which stop against the cross-guide. *Fig.* 98 is a tool for getting up broken rods. It consists of a small cylindrical piece at bottom, which the broken rod slips through when it is lowered, and a small catch with a knife-edge, acted upon by a back-spring. In rising, the tool takes hold of the broken rod, and thereby enables the workmen at top to draw it up. Another tool for the same purpose is shown at *fig.* 99, which is like a pair of tongs; it is intended to be slidden down the bore, and for the broken rod to pass between the two catches, which, pressed by back-springs, will, when drawn up, take fast hold of the broken rod.

Fig. 100 is a tool for widening the hole, to be connected, like all the others, to the end of the length of rods passed down the bore; this tool has two cutting-pieces extending on the sides at bottom, by which, as the tool is turned round in the bore, the earth is peeled away. *Fig.* 101 is a chisel, or punch, with a projecting piece to be used for penetrating through stone; this chisel is, by rising and falling, made to peck the stone, and pulverise it; the small middle part breaking it away first, and afterwards the broad part coming into action. *Fig.* 102 is another chisel, or punching tool, twisted on its cutting edge, which breaks away the greater portion of the stone as it beats against it.



The manner of forcing down lengths of cast-iron pipe, after the bore is formed, is shown at *fig.* 103; the pipe is seen below in the socket, at the end of which a block is inserted; and from this block a rod extends upwards, upon which a weight at top slides. To this weight cords are shown to be attached, reaching to the top of the bore; where the workmen alternately raise the weight and let it fall, which, by striking upon the block in its middle, beats down the pipe by a succession of strokes; and when one length of pipe has, by these means, been forced down, another length is introduced into the socket of the former. Another tool for the same purpose is shown at *fig.* 104, which is formed like an acorn; the raised part of the acorn strikes against the edge of the pipe, and by that means it is forced down the bore. When it happens that an auger breaks in the hole, a tool similar to that shown at *fig.* 105 is introduced; on one side of this tool a curved piece is attached, for the purpose of a guide, to conduct it past the cylindrical auger; and at the end of the other side is a hook, which, taking hold of the bottom edge of the auger, enables it to be drawn up.

Wrought iron, copper, tin, and lead pipes are occasionally used for lining the bore; and as these are subject to bends and bruises, it is necessary to introduce tools for the purpose of straightening their sides. One of these tools is shown at *fig.* 106, which is a bow, and is to be passed down the inside of the pipe, in order to press out any dents. Another tool for the same purpose is shown at *fig.* 107, which is a double bow, and may be turned round in the pipe for the purpose of straightening it all the way down; at *fig.* 108 is a pair of clamps, for turning the pipe round in the hole while driving.

When loose stones lie at the bottom of the hole which are too large to be brought up by the cylindrical auger, and cannot be conveniently broken, then it is proposed to introduce a triangular claw, as *fig.* 109, the internal notches of which take hold of the stone, and, as the tool rises, bring it up. For raising broken rods, a tool like *fig.* 110, is sometimes employed, which has an angular claw that slips under the shoulder of the rod, and holds it fast while drawing up.

In raising pipes, it is necessary to introduce a tool into the inside of the pipe, by which it will be held fast. *Fig.* 111 is a pine-apple tool for this purpose; its surface is cut like a rasp, which passes easily down into the pipe, but catches it as it is drawn up; and by that means brings the pipe with it. *Fig.* 112 is a spear for the same pur-

Digitized by Google

pose, which easily enters the pipe by springing; at the ends of its prongs there are forks, which stick into the metal as it is drawn up, and thereby raise it.

These are the new implements for which the patent was granted. In the process of the boring, there does not appear to be anything new proposed; but that these several tools are to be employed for boring, pecking, and otherwise penetrating, raising the earth, and extracting broken or injured tools. There are also suggestions for employing long buckets, with valves opening upward in their bottoms, for the purpose of drawing water from these wells when the water will not flow over the surface; also lift pumps with a succession of buckets for the same purpose. But as these suggestions possess little if any novelty, it cannot be intended to claim them as parts of the patent.

The so-called primary formations are seldom favourable to the construction of Artesian wells, on account of the compact massiveness of their rocks, and of the rarity of filtering strata overlying retentive ones. It is therefore vain to attempt the formation of an overflowing spring, upon the above principles, in territories of granite, gneiss, mountain limestone, and basalt. The hot springs which burst out of the ground in primary districts come undoubtedly from a great depth under the surface, and derive their heat, and also probably their waters, from an exalted subterranean temperature; but it would not be practical to bore to such extreme depths as would be necessary in these rocks. A miniature representation of such springs is exhibited in the intermitting fountains of fresh water on the shoulder of Vesuvius.

The most remarkable example of an Artesian well is that at the *abattoir* of Grenelle, a suburb of the south-west of Paris, where there was a great want of water. It cost eight years of difficult labour to perforate. The geological strata round the French capital are all of the tertiary class, and constitute a basin similar, in most respects, to that upon which London stands. The surface at Grenelle consists of gravel, pebbles, and fragments of rock, which have been deposited by the waters at some period anterior to any historical record. Below this layer of detritus, it was known to the engineer that marl and clay would be found. Underneath the marl and the clay, the boring rods had to perforate pure gravel, plastic clay, and finally chalk. No calculation from geological data could determine the thickness of this stratum of chalk, which, from its powers of resistance, might present an almost insuperable obstacle. The experience acquired in boring the wells of Elbeuf, Rouen, and Tours was in this respect but a very imperfect guide. But supposing this obstacle to be overcome, was the engineer sure of finding a supply of water below this mass of chalk? In the first place, the strata below the chalk possessed all the necessary conditions for producing Artesian springs, namely successive layers of clay and gravel, or of pervious and impervious beds. M. Mulot, however, relied on his former experience of the borings of the wells at Rouen, Elbeuf, and Tours, where abundant supplies of water had been found below the chalk, between similar strata of clay and gravel, and he was not disappointed.

M. Arago had shown that the water of the spring here would necessarily rise to the surface, because in the well at Elbeuf, which is nearly 9 yards above the level of the sea, the water rises from 27 to 29 yards above the surface of the earth, and consequently, from 36 to 38 yards above the ocean level. Now, as the orifice of the bore at Grenelle is only 34 yards above the same level, it followed that, if the identical water-bed was met with, the water would rise above the earth's surface at Grenelle.

The necessary works were commenced with boring rods about 9 yards long, attached to each other, and which could be raised or lowered by mechanical power, while an ingenious method was adopted for giving them a rotary motion. The diameter of the tube at the top of the bore is 11 inches and at the bottom 6·63 inches, according to M. Rey. The instrument affixed to the end of the lowest boring rod was changed according to the different strata which were successively attacked: the form suited for passing through the softer materials near the surface being unsuitable for boring through the chalk and flint, a hollow tube was used for the former, while a chisel-shaped tool was employed to penetrate the latter. The size of the rods was lessened as the depth increased; and, since the subterranean water was not reached so soon as was expected, it became requisite to enlarge five several times the diameter of the bore, in order to permit the work to be successfully prosecuted. Accidents occurred which tried the patience of the projectors. In May, 1837, when the boring had extended to a depth of 418 yards, the hollow tube, with nearly 90 yards of the long rods attached to it, broke and fell to the bottom of the hole, whence it became necessary to extract the broken parts before any further progress could be made. The difficulty of accomplishing this task may be conceived; for the different fragments were not all extracted until after the constant labour of 15 months. Again, in April 1840, in passing through the chalk, the chisel attached to the boring rod got detached,

Digitized by Google

and before it could be recovered, several months were spent in digging round about it. A similar occurrence again created an obstacle which impeded the work for 3 months, but instead of withdrawing the detached part, it was forcibly driven down among the stratum of gravel. At length, in February, 1841, after 8 years' labour, the rods suddenly descended several yards, having pierced into the vault of the subterranean waters so long sought after by the indefatigable engineer. A few hours afterwards, he was rewarded for all his anxious toils; for lo! the water rose to the surface, and discharged itself at the rate of 881,884 gallons in every 24 hours; the temperature of the water being nearly 82° F. At first it brought up so great a quantity of sand that the tube was several times choked up by it, and even now it is not free from occasional, though rare interruptions, but the force of the column of water has always proved sufficient to clear its way after a short interval. The water flows in a clear continuous stream, and is carried by pipes to a reservoir near the Pantheon, whence it is distributed over the adjacent parts of the city, as well as along the line of the Boulevards from the *abattoir* to the Observatory. By means of small pipes, also the École Militaire, the Invalides, and two or three other public establishments, are supplied with this water.

The strata traversed in forming this celebrated well were as follows:—

Drift-sand and gravel		33 feet.
Lower tertiary strata		115 „
Chalk with flints	1148	1394 „
Ditto, lower	246	
Calcareous sandstone, clays, and sands ending in a bed of green-coloured sand		256 „
		1798 „

The surface of the ground at the well is 102 feet above the level of the sea, and the water is capable of being carried above this to a height of 120 feet.

The French geologists consider that the sands from which the supply is obtained are either subordinate beds of *the gault*, or as belonging to the *lower greensand*. They crop out in a zone of country about 100 miles eastward of Paris, and range along the segment of a circle, of which Paris is the centre, from between Sancerre and Auxerre, passing near to Troyes, thence by St. Dizier to St. Ménéhould. The outcrop of this formation is continued some distance further north; it is also prolonged beyond Sancerre, south-westward towards Bourges, Chatellerault, and then north-west to Saumur, Le Mans, and Alençon. But the superficial area which it occupies in in these latter districts does not appear to contribute to the water supply of Paris, for the axis of elevation of Mellerault must intercept the subterranean passage of the water from the district south of that line, whilst, on the north of Paris, the anticlinal line of the "Pays de Bray" and some smaller faults in the Aisne, produce probably a similar stoppage with respect to the northern districts. The superficial area, therefore, from which the strata at the well of Grenelle draw their supplies of water, forms on the east of Paris a belt stretching from near Auxerre to St. Ménéhould.

The exposed surface of the water-bearing beds which supply the well of Grenelle is about 117 square miles; the subterranean area in connection with these lines of outcrop may possibly be about 20,000 square miles, and the average thickness of the sands of the *grès verts*, serving in their underground range as a reservoir for the water, does not probably exceed 30 or 40 feet.—*Prestwich on the Water-bearing Strata of London.*

The opportunity of ascertaining the temperature of the earth at different depths was not neglected during the progress of the works at Grenelle. Thermometers placed at a depth of 30 yards in the wells of the Paris Observatory invariably stand at 53° F. The temperature of the Artesian well at Grenelle at 1657 feet is 79° 5′, at 1800, the depth finally arrived at, the temperature of the water which rose to the surface was 81°, corroborating previous calculations on the subject. For a descent of 572 yards there is an increase of temperature equal to 28° F., which is 20·4 yards, or 61·2 feet, for each degree of that scale. Now that the skilful labour of so many years is terminated, the Parisians regret that the subterranean sheet of water had not lain 1000 yards beneath the surface, that they might have had an overflowing stream of water at 104°, to furnish a cheap supply to their numerous hot-bath establishments. In Westphalia, at 2000 feet, 90° 95′ F. was the temperature of the water.

In boring Artesian wells through stratified formations, several sheets of water are met with at successive heights; as at Saint Ouen there are 5, each capable of rising. one of these is at 36 metres of depth; a second at 45½ m., a third at 51½ m., a fourth at 59·30 m., and a fifth at 66½ m. (*the metre being* 3·280 *English feet.*) At Tours there are 3 sheets susceptible of rising above the surface, at 95, 102, and 125 metres respectively

Digitized by Google

beneath it. Seven large sheets of fresh water were in like manner observed in boring for coal near Dieppe. The deepest sheet, having the greatest superincumbent pressure, in general gives the highest hydrostatic level. The quantity of water furnished by such wells seems to be nearly constant: thus the well of Bages, near Perpignan, delivers nearly 3000 pints per minute, and that at Tours about 2000 pints at 6½ feet above the level of the ground.

As the cost of these wells is an important consideration, the following statement from the "Water-bearing Strata of London" is of much value.

"M. Dégoussée has recently informed me of his having contracted to bore an Artesian well at Rouen to the depth of 1080 feet (through the lower cretaceous and oolitic series) for 1600*l.*, expenses of every kind to be defrayed by him. M. Dégoussée has constructed three Artesian wells in different parts of France, of about 820 to 830 feet each, at an expense, including tubes and all expenses, of from 600*l.* to 1000*l.* The Calais well offers a very near counterpart of the deposits which occur beneath London, but the difficulties of the first 240 feet much exceeded those which would be met with here, and the chalk is probably 100 to 200 feet thicker. Here and at Paris the first 1000 feet cost less than 3000*l.*, and at Doncherry apparently not much more than 2000*l.*"

The following Table shows the cost of several of the Artesian wells of France :—

Grenelle,	Dept.	Seine	1798 feet	-	-	£14,500
Calais	„	Pas de Calais	1138 „	-	-	3,560
Donchery	„	Ardennes	1215 „	-	-	3,045
St. Fargeau	„	Yonne	666 „	-	-	1,216
Lille	„	Nord	592 „	-	-	320
Crosne	„	Seine and Oise	333 „	-	-	190
Brou	„	Marne	246 „	-	-	200
Ardres	„	Nord	155 „	-	-	64
Claye	„	Seine and Marne	108 „	-	-	78
Chaville	„	Oise	65 „	-	-	15

It appears that, in England, the cost of boring is about 5*s.* for the first 10 feet, 2*l.* 10*s.* for forty feet, 5*l.* 5*s.* for 60 feet, 13*l.* 15*s.* for 100 feet, and so on in proportion.

Mr. Landall of Edinburgh informs us, that in Scotland they reckon 100 or 110 fathoms a very deep bore; and it is all done with the old screwed rods and chisels. "I have," he says, "once or twice worked the lever with a steam-engine, and cleaned the bore with a wire rope fixed to the sluger, and a few lengths of rod to make it sink quickly, which is a very great economy, as it saves the screwing and unscrewing and much handling. When the bore is approaching 100 fathoms, it is a great economy to erect a small engine, and clean with a wire rope."

The following particulars relative to the conditions of some Artesian wells in this country are derived from Sir Charles Lyell's "Principles of Geology," where the geological question is fully treated.

At Sheerness, at the mouth of the Thames, a well was bored through 300 feet of London clay, when, on entering a bed of sand, water burst up impetuously. Another boring at the same place passed through 328 feet of clay, and water ascended eight feet above the level of the ground.

At Fulham, after penetrating to the depth of 317 feet, 67 feet of which were in chalk, water was discharged at the rate of 60 gallons a minute.

At Chiswick the borings passed through 19 feet of gravel, 242½ feet of clay and loam, and 67½ feet of chalk, when water rose to the surface.

At the Duke of Northumberland's, at Chiswick, the borings were carried 620 feet into the chalk, when water rose four feet above the surface.

The deep wells of London are all in the chalk. The depths of some of the most important are given in Mylne's "Section of the London Strata," as follows :—

	Depth.
Combe and Co.	522 feet
Excise Office, City	499 „
Plummer, Old Street	475 „
Meux and Co.'s Brewery	425 „
Hampstead Water Works	450 „

It appears desirable to collect, within a limited compass, all the available information of importance in connexion with this subject. Mr. William Whitaker, of the Geological Survey of Great Britain, has published a memoir on "*The Geology of Parts of Middlesex, Hertfordshire, Buckinghamshire, Berkshire, and Surrey*," full of valuable information. In the appendix to this memoir, he has given an abstract table of well sections, shewing the thickness of the different strata, and the total depth of the sinkings. From this table I have selected the more important wells, which show in a satisfactory manner the conditions of the country through which they have been sunk which Mr. Whitaker has kindly corrected.

Sections of some of the Deep Wells in London and the adjoining Country. See Sheet 7 of the Map of the Geological Survey of Great Britain.

The Artesian wells in Essex, which overflow, are of the following depths, according to Dr. Mitchell: —

Foulness Island	450 feet
Mersey and adjoining Islands	300 „
Wallis Island	400 „
Little Wigborough	250 „
Woodham	350 „
North Ockenden	80 „
Fobbing	100 „
Bulpham Fen	70-80 „

The question of water supply to the metropolis depends upon the situation of the most advantageous water-bearing deposit, or, as Mr. Prestwich states it, the extent of the superficial area occupied by the water-bearing deposit.

The lithological character and thickness of the water-bearing deposit, and the extent of its underground range.

The position of the outcrop of the deposit, whether in valleys or in hills; and whether its outcrop is denuded, or covered with any description of drift.

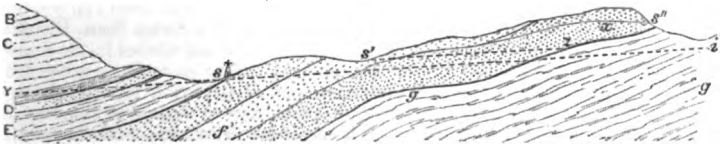
The general elevation of the country occupied by this outcrop above the levels of the district in which it is proposed to sink Artesian wells.

The quantity of rain which falls in the district under consideration, and whether, in addition, it receives any portion of the drainage from adjacent tracts, where the strata are impermeable.

The disturbances which may affect the water-bearing strata and break their continuity, whereby the subterranean flow of water would be impeded or prevented.

It is proposed, by the eminent authority we have already quoted, to bore through the chalk of the London basin, and penetrate the lower greensand formation.

113



Referring to the former section across London (*fig.* 82), and then examining *fig.* 113, the importance of this suggestion will be evident. B is the lower tertiary strata, C is the chalk, D the upper greensand, E the gault, and *f* the lower greensand, *g* the upper part of the wealden formation, Y *i* line of the lowest valley of the district, and *s s' s''* line of water-level and springs. The edges of this formation are bounded on the north by the gault at *s*, and on the south by the wealden at *s''*. They are both impermeable strata, and present water-tight surfaces to the sand between them, so that any water which might find its way below the margins of these deposits could not escape again, but would follow the subterranean course of the intermediate strata.

After computing with great care the quantity of rain falling over the district, Mr. Prestwich gives the following Table, the result of his investigations: —

	Probable extent of effective Area.	Quantity of Rain Water received.	Probable Quantity absorbed.
	Sq. miles.	Inches annually. Gallons in 24 hours.	Inches annually. Gallons in 24 hours.
Lower Tertiaries	24	25 = 23,749,656	12 = 11,411,352
Upper Greensand	70	28 = 77,660,660	10 = 27,735,960
Lower Greensand	230	26½ = 241,500,920	16 = 145,811,720

"These calculations, although offered as only very general approximations, give results sufficiently marked and decided, that even admitting the necessity of not inconsiderable corrections, I think they establish strong *prima facie* evidence in favour of the upper and lower greensands beneath London containing unusually large quantities of water, which may be rendered available for the supply of the metropolis by means of Artesian wells. What their yield might be could only be determined exactly by actual experiment; but, judging from analogy, if the lower tertiary sands, with dimensions comparatively so limited, can nevertheless furnish not less than 3,000,000 to

Digitized by Google

4,000,000 gallons daily (and if, as is probable, they supply much of the water found in the upper beds of the chalk beneath London, their yield may amount to 8,000,000 or 10,000,000), then I submit that there is a reasonable probability, after allowing for the present over-drainage of the tertiaries of the upper greensand, with an effective area and a thickness three times greater than those of the lower tertiaries, yielding daily, and without diminution, from 6,000,000 to 10,000,000, and of the lower greensands, which exceeds by ten times the lower tertiaries in both these respects, of their yielding daily and without diminution from 30,000,000 to 40,000,000 gallons of water in the 24 hours, taken at about surface level."*

Since the beds of the lower greensand are 200 feet thick, and they occupy an area above and below ground of 4600 square miles, and since a mass of 1 mile square and 1 foot thick will hold more than 60,000,000 gallons of water, it is evident that a year's consumption of water, by the population of London, would not occasion a fall of 1 foot in the water-level over the entire area; that is, supposing no rain had fallen during the year. Such wells, too, would have the advantage of adding to the adornment of the metropolis; as, if the water of the lower greensand was liberated by means of Artesian wells, fountains would be at once formed projecting their water from 100 to 150 feet above the level of Trinity high water mark. See BORING for details of process.

ARTESIAN WELLS, *Negative*. Borings into the earth which are intended to carry off the waters from the surface. They have been proposed for the purpose of draining large tracts of swampy country. Especial information on this subject will be found in the "Society of Arts' Journal" for 1856, and Anstead's "Geology."

ARTICHOKE (*Cynara Scolymus*). A thistle-like plant, a native of the South of Europe, cultivated for the sake of the fleshy sweet receptacle of its flowers. JERUSALEM ARTICHOKES are the tubers of the *Helianthus Tuberosus*, and derive their name by a corruption, from the Italian *girasole*, sunflower.

ARTILLERY. The earliest European artillery of large size consisted of "serpentines" and "bombards," both being formed of longitudinal bars of wrought-iron, arranged like the staves of a cask, and hooped all over, or nearly so, with wrought-iron rings, shrunk on hot upon the bars. The serpentine was of small calibre, but of enormous length. A gun of this character, taken by the Swiss from Charles le Téméraire, at the battle of Granson, in 1476, is described and figured in the Emperor Napoleon's work, "Passé et l'Avenir d'Artillerie." This example is preserved in the collection of the Arsenal of Neuville, canton of Berne; it is only about two inches calibre, but about ten feet in length of chase, formed with wrought-iron, with rings shrunk on at some inches apart. It is embedded to its horizontal diameter, and for its whole length, in a timber bed.

The bombard was usually a much shorter piece, often of immense calibre. The great gun of Ghent, known as *Dulle Griette*, or the Raging Meg, is of this character. Voisin thus describes it:—"This enormous cannon, or ancient bombard, is one of the most curious pieces of artillery known, both in dimensions and construction, which is a *chef d'œuvre* of the art of forging. It is 18 feet in length, by 10 feet 6 inches in circumference, the mouth is 2¾ feet in circumference; it is forged from bars of iron, and weighs 33,606 lbs., and throws a stone ball of 600 lbs. weight. Its construction appears to date from the early years of the invention of artillery; in all probability it was forged while Philippe Van Artevelde, Riswaert of Flanders, was besieging Oudenarde, in 1382. It is certain that the people of Ghent, at war with their duke, Philippe, used it in 1411, and at the attack of Oudenarde, in 1452."

In the arsenal of St. Petersburg is a bombard which is 21 feet long; but it only weighs 17,435 lbs., and its calibre is only 68 lbs.

The Mons Meg of Scotland, which now quietly reposes on the King's Bastion, Edinburgh, is formed of longitudinal stave bars, in one ply only, and of superimposed rings, driven and shrunk on upon the taper. This will be understood from the accompanying figures (114, 115). This gun was made by one M'Kin, to whom the people of Kirkcudbright contributed the bars of iron. Mons Meg was used at the siege of Dumbarton, in 1489; at Norham, in 1497; it was used to fire a salute in 1548; and in 1682, when firing a salute in honour of the Duke of York, the iron rings, which are now partly wanting near the breach, were blown away without much disturbing the longitudinal bars. The gun actually discharged balls of Galloway granite against Threave Castle. The weight of a granite ball of 19½ inches diameter is about 330 lbs.

Colonel Symes, in his "Embassy to Ava in 1795," informs us that he found that cannon formed of prismatic bars of wrought hoop-iron hooped together were known

* Consult Prestwich, Water-bearing Strata of the Country around London; Mylne's Sections of the London Strata; M. Garnier's Traité sur les Puits Artésiens; Swindell, Rudimentary Treatise on Well-digging, Boring, &c.

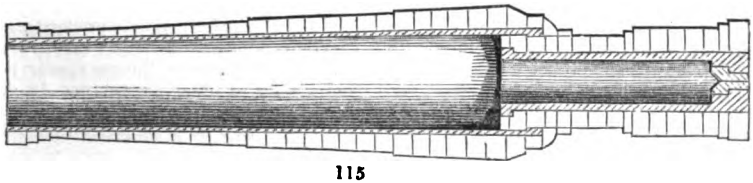
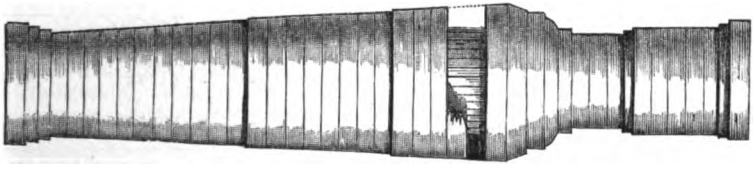
in India from a remote antiquity. In Meyer's "Historical Manual" will be found a curious history of the progress of wrought-iron cannon, from 1494—when Charles VIII. suppressed wrought-iron bombards, and had no other artillery than that of bronze—to

114



115



the present day. In 1856, Daniel Treadwell published a memoir "On the Practicability of constructing Cannon of great Calibre capable of enduring long-continued Use under full Charges." In this he proposes a very large wrought-iron gun, which should be capable of projecting a shot or shell of a ton weight through the space of six miles. He says, in a note to this paper, "Between the years 1841 and 1845, I made upwards of twenty cannon of this material (wrought iron). They were all made up of rings, or short hollow cylinders, welded together endwise. Each ring was made of bars wound upon an arbour spirally, like winding a ribbon upon a block, and, being welded and shaped in dies, were joined endwise when in the furnace and at a welding heat, and afterwards pressed together in a mould by a hydrostatic press of 1000 tons force." Finding in the early stage of the manufacture that the softness of the wrought iron was a serious defect, he formed those made afterwards with a lining of steel, the wrought-iron bars being wound upon a previously formed steel ring.

Mr. Nasmyth undertook, in 1854, an enormous wrought-iron gun of 13 inches calibre; but there was some failure in the forging.

In 1856, Messrs. Horsfall, of Liverpool, completed, and proved with a solid shot of 300 lbs. and 45 lbs. of powder, a wrought-iron gun, 13 inches calibre, and 13½ feet length of chase, perhaps the largest and most remarkable forging ever made. Two wrought-iron mortars, of 36 inches calibre, built up of separate pieces, were constructed about the same time for the Government, from the designs of Mr. Mallet. A detailed account of this monster mortar is given at page 208.

Cast-Iron Guns. — The date of the introduction of cast-iron guns is very uncertain. Blast furnaces for smelting replaced the old Catalan methods about the commencement of the fifteenth century, were known in the Hartz, in Westphalia, in Flanders, and seem to have come to us thence, and were not uncommon about the middle of the century. There is in the repository at Woolwich an 18-inch *Pierrière*, captured at Corfu, with the date 1684 upon it, an early example of cast iron.

In the sixteenth and seventeenth centuries the average sizes of guns in England were as follows:—

	Length. feet.	Calibre. lbs.	Weight. lbs.
The cannon royal, or piece of eight	12	48	8000
The demi-cannon	12	36	6000
The culverin	12	20	4800
The demi-culverin	11	10	2700
The saker	10	6	1500

The smaller sizes were called minion, falcon, falconet, rabinet, and base, the last of which only carried a 5-ounce ball of lead.

Cannon of Bronze.—The earliest bronze guns appear to have been cast in Europe about 1370. Between that and 1400, bombards were cast (after the more ancient models of iron) in bronze with separate and with attached chambers (*canons à boîte*), the ancestors of all modern breech-loading guns; and culverins, which replaced the

Digitized by Google

iron serpentines, and were of enormous length, 35 to 60 calibres, and great strength towards the breech, but of small calibre. Many examples remain of a later date: one at Dover Castle, another in the Dial Square, Woolwich Arsenal, and the celebrated one of Nancy (1598), above 21 feet in length, carrying about an 18-pound iron ball. In England, the earliest bronze guns are said to have been cast by one John Owen, in 1535.

Few examples are met with of guns formed of metal in strictly atomic proportions; but alloys are found therein presenting every formulæ, from 7Cu + Sn up to 83Cu + 4Sn. The proportions most approved of in the arsenals of Europe appear to vibrate between 100 by weight of copper to 9 of tin, up to 100 of copper and 12 of tin. In France, 100 copper + 11 tin by weight is the proportion fixed by law, and invariably aimed at. In the United States, 100 copper + 12·5 tin is adopted for certain species of guns.

The proportions of tin and copper used in making bronze guns in the United States:—

	Density.	Tenacity.
Tin, 1 part	7·297	2122
Copper, 8 parts	8·672	24252
Mean proportional	8·519	21793
Mean of 83 guns	8·751	
Mean of 83 gun-heads	8·523	29655

Bronze guns are liable to drop at the muzzle; this is due to the unequal temperature of the inside and of the outside of the gun.

Brass ordnance are made of what is called GUN METAL, composed of about 10 parts of copper and 1 of tin.

One of the first inquiries of importance in connection with the construction of pieces of artillery is that of the liability to fracture in the metal. Upon this point the researches of Mr. Mallet furnish much important matter. He tells us, as the result of his investigation, that *it is a law of the molecular aggregation of crystalline solids, that when their particles consolidate under the influence of heat in motion, their crystals arrange and group themselves with their principal axes in lines perpendicular to the cooling or heating surfaces of the solid: that is, in the lines of the direction of the heat-wave in motion, which is the direction of least pressure within the mass.* And this is true, whether in the case of heat *passing from* a previously fused solid in the act of cooling and crystallising in consolidation, or of a solid not having a crystalline structure, but capable of assuming one upon its temperature being sufficiently raised, by heat applied to its external surfaces, and so *passing into* it.

Cast-iron is one of those crystallising bodies which, in consolidating, obeys, more or less perfectly according to conditions, the above law. *In castings of iron the planes of crystallisation group themselves perpendicularly to the surfaces of external contour.* Mr. Mallet, after examining the experiments of Mr. Fairbairn — who states ("Trans. Brit. Ass." 1853) that the grain of the metal and the physical qualities of the casting improve by some function of the number of meltings; and he fixes on the thirteenth melting as that of greatest strength — shows that the size of crystals, or coarseness of grain in castings of iron, depends, for any given "make" of iron and given mass of casting, upon *the high temperature of the fluid iron above that just necessary to its fusion, which influences the time that the molten mass takes to cool down and assume again the solid state.*

The very lowest temperature at which iron remains liquid enough fully to fill every cavity of the mould without risk of defect, is that at which a large casting, such as a heavy gun, ought to be "poured." Since the cooling of any mass depends upon the thickness of the casting, it is important that sudden changes of form or of dimensions in the parts of cast-iron guns should be avoided. In the sea and land service 13-inch mortars, where, at the chamber, the thickness of metal suddenly approaches twice that of the chase, is a malconstruction full of evils.

The following statements of experiments made to determine the effect produced on the quality of the iron in guns, by slow or rapid cooling of the casting, are from the report of Major W. Wade, of the South Boston Foundry, to Colonel George Bomford, of the Ordnance Department of the United States. Three six-pounder cannon were cast at the same time from the same melting of iron. The moulds were similar, and prepared in the usual manner. That in which No. 1 was cast was heated before casting, and kept heated afterwards by a fire which surrounded it, so that the flask and mould were nearly red hot at the time of casting; and it was kept up for three days. Nos. 2 and 3 were cast and cooled in the usual way.

At the end of the fourth day, the gun No. 1 and flask were withdrawn from the

Digitized by Google

heating cylinder while all parts were yet hot. Nos. 1 and 2 were bored for 6-pounders in the usual way; No. 3 for a 12-pounder howitzer, with a 6-pounder chamber. The firing of the guns was in every respect the same. Nos. 1 and 2 were fired the same number of times with similar charges. No. 1 burst at the 27th fire, and No. 2 at the 25th. It appears, from these results, that no material effect is produced on the quality of the iron by these different modes of cooling the castings.

A very extensive series of experiments was made, by the order of the United States Government, on the strength of guns cast solid or hollow. In these it was confirmed that the guns cast hollow endured a much more severe strain than those cast solid. Considerable differences were also observed, whether the casting was cooled from within or without; and Lieutenant Rodman's method of cooling from the interior is regarded as tending to prevent injurious strains in cooling.

Major Wade informs us that time and repose has a surprising effect in removing strains caused by the unequal coolings of iron castings.

Great improvements have been made in improving the quality of iron guns. Guns cast prior to 1841 had a density of 7·148, with a tenacity of 23,638. Guns cast in 1851 had a density of 7·289, with a tenacity of 37,774.

The following Table gives the results of all the trials made for the United States Government, showing the various qualities of different metals.

Metals.	Density.	Tenacity.	Transverse Strength.	Torsion.		Compressive Strength.	Hardness.
				At Half Degree.	Ultimate.

An inspection of the first of the foregoing tables, representing the average amount of each foreign ingredient in gun metal deduced from all the analyses, shows a considerable difference in the proportions of those ingredients in each of the three classes into which guns are divided. It will be observed, that while the proportion of combined carbon diminishes from the 1st to the 3rd class, that of silicium similarly increases, so that their united amounts are nearly the same. In other words, it appears that silicium can replace the carbon to a certain extent; but that the quality of the metal is injured where the amount of the silicium approaches that of the carbon. Karsten made a similar observation in determining the limits between cast iron and steel, but did not notice the influence of that substitution.

But the differences become more striking by combining the ingredients variously together, as in the second of those tables; and especially by comparing the extremes, which are each derived from a larger number of observations than the mean.

After showing the total amount of carbon (both combined and uncombined), silicium and conbined carbon are thrown together, which indicates the replacement by silicium of that portion of carbon set free in the form of graphite. The column "silicium and slag" shows the general depreciation of the metal as the silicious metal increases.—*From the Report of Campbell Morfit and James C. Booth to the Ordnance Office, United States Army.*

The following analyses (rejecting those substances of which only a mere trace has been discovered), from the same chemists, are selected as showing striking peculiarities.

Class.	Iron.	Graphitic Carbon.	Combined Carbon.	Silicium.	Slag.	Phosphorus.	Manganese.	Magnesium.	Calcium.	Aluminium.	Sodium and Potassium.

Comparison of Weight, Strength, Extensibility, and Stiffness; Cast Iron being unity within practical limits to static forces only.

Material.	Weight for = Volume.	Strength.	Extensibility.	Stiffness.	Torsion.
Cast iron - -	1·00	1·00	1·00	1·00	1·00
Gun metal - -	1·18	0·65	1·27	0·53	0·55
Wrought iron -	1·07	3·00	0·45	2·20	1·11
Steel - - -	1·07	4·75	0·32	3·15	2·11

We find that wrought-iron guns are more than five-fold as durable as those of gun metal, and twenty-two times as durable as those of cast iron. And taking first cost and durability together, gun-metal cannon are about seventy-seven times, and cast-iron guns about thirty times, as dear as wrought-iron artillery. Again: the cost of horse-labour, or other means of transport for equal strength (and, of course, therefore, for equal effective artillery power), is about five times as great for gun metal, and nearly three times as great for cast-iron as for wrought-iron guns. In every respect in which we have submitted them to a comparison, searching and rigid, and that seems to have omittted no important point of inquiry, wrought iron stands pre-eminently superior to every other material for the fabrication of ordnance.—*United States Report.*

The advantages possessed by rolled bars for the construction of artillery are thus summed up by Mr. Mallet, in his "Memoir on Artillery":—

1. The iron constituting the integrant parts is all in moderate-sized, straight, prismatic pieces, formed of rolled bars only; hence, with its fibre all longitudinal, perfectly uniform, and its extensibility the greatest possible, and in the same direction in

Digitized by Google

which it is to be strained; it is, therefore, a better material than any forged iron can, by possibility, be made.

2 The limitation of manufacture of the iron, thus, to rolling, and the dispensing with all massive forgings, insures absolute soundness and uniformity of properties in the material.

3. The limited size of each integrant part, and the mode of preparation and combination, afford unavoidable tests of soundness and of perfect workmanship, step by step, for every portion of the whole: unknown or wilfully concealed defects are impossible.

4. Facility of execution by ordinary tools, and under easily obtained conditions, and without the necessity of either for peculiarly skilled labour on the part of "heavy forgemen," or for steam or other hammers, &c., of unusual power, and very doubtful utility; and hence very considerable reduction in cost as compared with wrought-iron artillery forged in mass.

5. Facility of transport by reduction of weight, as compared with solid guns of the same or of any other known material.

6. A better material than massive forged iron, rolled bars are much more scientifically and advantageously applied; the same section of iron doing much more resisting work, as applied in the gun built-up in compressed and extended plies, than in any solid gun.

7. The introduction thus into cannon of a principle of elasticity, or rather of elastic range (as in a carriage-spring divided into a number of superimposed leaves), greater than that due to the modulus of elasticity of the material itself; and so acting, by distribution of the maximum effort of the explosion, upon the rings successively recipient of the strain during the time of the ball's traject through the chase, as materially to relieve its effects upon the gun.

Considerable attention has been given, of late years, to the construction of very powerful pieces of ordnance. Cast-iron cannon are usually employed, but these very soon become useless when exposed to the sudden shocks of rapid firing. Cast iron is, comparatively speaking, a weak substance for resisting extension, or for withstanding the explosive energy of gunpowder, compared with that of wrought iron, the proportion being as 1 is to 5; consequently, many attempts have been made to substitute wrought-iron cannon for cast.

A gun, exhibited in 1851 by the Belgian Government, made of cast iron "*prepared with coke and wood*," was said to have stood 2116 rounds, and another, 3647 rounds, without much injury to the touch-hole or vent. Another is said to have been twice "rebouched," and has stood 6002 rounds without injury. As few guns of cast iron will stand more than 800 rounds without becoming unserviceable, this mode of preparing the iron appears to be a great improvement. At St. Sebastian 2700 rounds were fired from the English batteries, but, as was observed by an eye-witness, "you could put your fist into the touch-holes."—*Colonel James*, R. E.

In Prussia they have for some time made cannon of "forged cast steel." To get over the difficulty of forging the gun with the trunnions on, the gun has been made without them, and a hollow casting with trunnions afterwards slipped over the breech, and secured in its proper position by screening in the cascable. The tenacity of this metal must be very great.

Casting of Guns.—Guns have long been cast in a vertical position, and with a certain amount of "head of metal" above the topmost part of the gun itself. One object gained by this (of great value) is to afford a gathering-place for all scoria, or other foreign matter; an end that might be much more effectually accomplished were the metal always run into the cavity of the mould by "gaits" leading to the bottom, or lowest point, in place of the metal being thrown in at the top, with a fall, at first, of several feet, as is now the common practice, by which much air and scoria are carried down and mixed with the metal, some of which never rises up again, or escapes as "air-bubbles."

The value of the "head of metal" in casting of guns is shown by the following Table, by Mr. Mallet, from the "Transactions of the British Association, 1840."

General Classification of the principal Makes of British Cast Irons as applicable to Artillery.
(All deduced from equal Pieces cast One Inch thick and Five Inches square.)

Number.	Class of Iron.	Hot or Cold.	Commercial No.	Fracture.	Character in Working.	Sp. Gr.	How Cast.	Physical Maxima and Minima.
1	Apedale - -	Cold	No. 2	Silvery	Least fusible; thickening rapidly when fluid by a spontaneous "puddling," vesicular, often crystalline, incapable of being cut by chisel or file; ultimate cohesion a maximum, and elastic range generally a minimum.	7·603	Chilled	
2	Hardest Procurable.		Scrap	,,		7·624	Sand	Maximum density.
3	Oldberry - -	Hot	No. 3	,,		7·501	Sand	Coefficient E nearly as in No. 22.
4	Ponkey - -	Cold	No. 3	,,		7·233	Sand	Maximum ultimate strength and value of Te. nearly as in No. 40.
5	Pentwyn - -	Hot	No. 2	,,		7·629	Chilled	
6	Calder - - -	Hot	No. 4	,,		7·527	Sand	
7	Shotts - - -	Hot	No. 4	,,		7·158	Sand	
8	Dowlais (Finery Pig).	Hot	No. 4	,,		6·378	Sand	Full of microscopic vesicles.
9	Arigna - -	Cold	No. 1	Micaceous	Very soft; feels greasy; peculiar micacious appearance, generally owing to excess of manganese; soils the fingers strongly, crystals large; runs very fluid; contraction large.	7·015	Sand

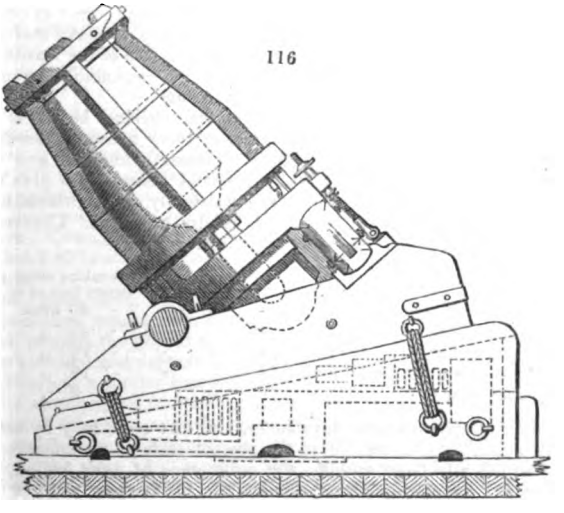
8	168	7·1035	·0128	168	7·1430	·0142	168	7·1183	·0137	44·8

The experiments were made upon cylindrical shafts of cast iron, cast vertically in dry sand-mould, under heads gradually increasing up to fourteen feet in depth, and all poured from "gaits" at the bottom.

These experiments show an increase of density due to fourteen feet head, about equal to a pressure of 44·8 lbs. per square inch on the casting; from 6·9551 to 7·1035 for Scotch cast iron.



Mallet's mortar (fig. 116) is wholly formed of wrought-iron in concentric rings, and each mortar is separable at pleasure into 13 separate pieces, the heaviest weighing about 11 tons, the weight of the entire mass being 52 tons.

About the latter end of 1854, the attention of Mr. Robert Mallet, C.E., was directed to the mathemathical consideration of the relative powers of shells in proportion to their increase of size or of diameter. His inquiries resulted in a memoir presented by him to Government, in which he investigated the increase of power in shells with increase of diameter, under the heads of:—1, Their penetrative power; 2, Their increased range and greater accuracy of fire; 3, Their explosive power; 4, Their power of demolition, or of levelling earthworks, buildings, &c.; 5, Their fragmentary missile power; 6, and lastly, their moral effect,—in every case viewing the shell, not as a weapon against troops, but as an instrument of destruction to an enemy's works. The result so convinced Mr. Mallet of the rapid rate at which the destructive powers of a shell increase with increase of size, that he was induced to propose to Govern-

Digitized by Google

ment the employment of shells of a magnitude never before imagined by anyone, namely, of a yard in diameter, and weighing, when in flight, about a ton and a quarter each: and to prepare designs, in several respects novel and peculiar, for the construction of mortars capable of projecting these enormous globes. Such a mortar was made, and on the 19th of October, 1857, the first of those colossal mortars, constructed from Mr. Mallet's design, was fired on Woolwich Marshes, with charges (of projection) gradually increasing up to 70 lb.; and with the latter charge a shell weighing 2550 lbs. was thrown a horizontal range of upwards of a mile and a half to a height of probably three quarters of a mile, and falling, penetrated the compact and then hard dry earth of the Woolwich range to a depth of more than 18 feet, throwing about cartloads of earth and stones by the mere *splash* of the fall of the empty shell.

The position attained by Rifled Ordnance manufactured on the principles advocated by Sir William Armstrong is such, that it appears desirable that the clearest possible view should be given of the mode of constructing those guns. Sir William Armstrong himself so very clearly describes the principles by which he has been guided in the construction of his guns—that his paper communicated to the British Association, and reprinted in "The Industrial Resources of the Tyne, Wear, and Tees," has, with some slight alteration, been retained as the best possible source of information.

"In the month of December, 1854, my friend Mr. Rendell, the well-known engineer, submitted to Sir James Graham a communication he had received from me suggesting the expediency of enlarging the ordinary rifle to the standard of a field gun, and using elongated projectiles of lead instead of balls of cast-iron. This communication was handed by Sir James Graham to the Duke of Newcastle, then Minister of War, with whom I had an interview on the subject, in company with Mr. Rendell.

At this interview I was authorised by His Grace to carry my views into effect, by constructing upon the plan I had suggested one or more guns, not exceeding six in number, and to make the necessary experiments in connection with the subject.

In acting upon the authority thus received, I deemed it expedient to confine myself, in the first instance, to the production of a single gun, but to make that one gun the test, not only of the principles I had recommended, but also of the feasibility of loading field-pieces at the breech, and applying certain mechanical arrangements to counteract recoil, and facilitate the pointing of the gun.

The substitution of elongated solid projectiles for spherical bullets is an essential step to the attainment of very extended range in artillery practice: but the lengthening of a solid projectile involves the necessity of strengthening the gun to enable it to resist the greater intensity of force which becomes necessary to give the required velocity; and this object can only be effected, consistently with lightness, by constructing the gun of steel or wrought-iron instead of cast-iron or bronze. The tensile strength of these several materials is exhibited in the following table:—

	Breaking strain per square inch of section.
Cast-steel, about	60 tons.
Shear-steel	42 „
Wrought-iron	26 „
Bronze or gun metal about	16 „
Cast-iron	8 „

The first and strongest of these substances, viz. cast steel, may be set out of the question, as it appears impracticable, in the present state of manufacture, to produce it in masses sufficiently large without the occurrence of flaws, which, in the great majority of cases, would destroy its efficiency. Shear-steel may be forged, like wrought-iron, into large pieces: but in a gun made from a solid mass of either of these substances, the full strength of the material can never be realised, because the tenacity of wrought-iron or steel is always less in the lateral than in the longitudinal direction: and it is the lateral strength which, in a gun so manufactured, would be chiefly brought into action. There is also much uncertainty in the lateral strength of wrought iron or steel, because the flaws or imperfections of welding which exist in all thick masses of those materials almost invariably run in the direction of the length, and in general, therefore, only detract from the strength in the transverse direction. It is for these reasons that the barrels of muskets and sporting guns are formed by twisting long slips of iron into spiral tubes, and then welding together the edges, by which means the longitudinal strength of the slip becomes opposed to the explosive force of the powder, and the weldings being transverse with the bore, have no important influence in lessening the strength of the barrel. It is also to be observed, in reference to the strength of steel or wrought-iron cannon, that the resistance of a cylinder to internal pressure does not increase in the ratio of its thickness. If

Digitized by Google

the cylinder be regarded as made up of a number of concentric layers, each capable of sustaining without injury a degree of extension proportionate to its length, it is obvious, that the greater the circumference of each layer, the less will it be stretched by a given distention of the bore, and, consequently, the less will it contribute to the general strength of the cylinder. The ratio of this decrease is very rapid, being as the square of the circumference, or distance from the centre inversely; and, consequently, when the cylinder is thick, the deficiency of strength from this cause becomes very great.

Now this defect can only be remedied by giving to the external portion of the cylinder a certain initial tension, gradually decreasing and finally passing into compression towards the centre; and although this condition cannot be effected by any known process of forging or casting, yet where wrought-iron or steel is the material used, it may in a great measure be attained by shrinking an outer cylinder upon an inner one, and in like manner superadding others until the requisite thickness has been acquired.

The method, however, of forming steel or wrought-iron guns, by simply forging the material into the required form, and boring it in the usual manner, was so much recommended by its facility, that I was induced to make some experiments to test its sufficiency.

With this view a number of cylinders were forged, each twelve inches long and five inches in the outward diameter. These were bored to an internal diameter of one and three-quarter inches, and tested in the following manner:—Each cylinder was entirely filled with gunpowder, and the open end was pressed by screws against a very thick iron tube bored to the same diameter, and containing a cylindrical shot of lead equal in weight to about three spherical shot of the same diameter and material. Several of the cylinders burst on the first discharge, and those which remained uninjured were afterwards reduced in thickness, and tested a second time. If they still resisted the explosion, the thickness was further diminished; and this mode of proceeding was continued until fracture took place in all of them.

The results obtained in this manner showed, as had been apprehended, great uncertainty in the strength of the material, and rendered it impossible to define the thickness necessary to resist a given charge of powder. I felt compelled, therefore, to dismiss this mode of construction, and to adopt another more correct in principle, but more difficult of execution.

In the above experiment it was found that steel was more subject to defects of welding than iron; but being a harder substance, and therefore more fitted to form the surface of a bore, I determined to apply it as an internal lining, and to obtain the necessary strength by encircling it with twisted cylinders of wrought iron, tightly contracted upon the steel core by the usual process of cooling after previous expansion by heat. Considerable difficulties were encountered in carrying this plan into practice; but I ultimately succeeded in completing a gun, of which the following is a description.

The gun, when fired, recoils upon an ascending slide without displacing the carriage, and then returns to its place by gravity. The slide frame turns upon a pivot which permits the gun to be pointed to either side without moving the carriage. The gun is elevated and depressed by means of a screw, which is fixed to and moves with the slide, and a similar screw is applied for the traversing or horizontal movement. The arrangement for loading at the breech may be described as follows:—At the back end of the gun a powerful screw is applied, having a hole through the centre, forming a prolongation of the bore, and through which hole the bullet and charge are delivered into the gun. A "breech-piece" with a mitred face, fitting a similar face at the end of the bore, is then dropped into a recess, and by the action of the screw pressed tightly into its seat, so as effectually to close the bore.

In order to facilitate the loading, the bullet and cartridge are placed in a tube, from which they are thrust into the gun by means of a rammer.

The breech-piece contains a vent, with a cavity for receiving a small quantity of powder to ignite the charge; and as the breech-piece is prepared for firing while the gun is being loaded, no time is lost in subsequent priming.

Several of these breech pieces accompany the gun, some being arranged to fire by percussion caps, and others by friction tubes or port-fires.

The bore of the gun is one and three-quarter inches in diameter, and contains eight spiral grooves, having an inclination equal to one turn in twelve feet. These grooves terminate at a distance of fourteen inches from the breech, and the bore then gradually expands in a length of three inches, from one and three-quarters inches to one and seven-eighths inches in diameter. The bullet, in the operation of loading, passes freely through this widened space; but its diameter being a little in excess of the bore, it lodges in the tapered contraction at the commencement of the grooves.

Digitized by Google

The mode in which the gun is made up of separate parts consists in surrounding the steel centre with twisted cylinders of wrought-iron, made in a similar manner to gun barrels, and being shrunk upon the steel, they are in that state of initial tension which is necessary to bring their entire strength into operation.

The weight of the gun by itself is about 5 cwts.; but, including the carriage, its weight is nearly identical with that of a light 6-pounder with its carriage complete. It is probably heavier than necessary, but recoil might be inconveniently increased if the weight were much reduced.

Having now described the gun and its carriage, I shall proceed to speak of the projectile.

The resistance which a projectile encounters in passing through the air is mainly dependent upon the area of its cross section, and the advantage of lengthening a bullet consists in augmenting the weight without increasing this sectional area; but in order to realise this advantage it is essential that the bullet be guided endways in its course, and this can only be effected by causing it to rotate rapidly upon its longer axis, which is accomplished by firing it from a rifled bore.

This peculiar influence of rotation, in giving persistency of direction to the axis of a projectile, is entirely distinct from that which it also possesses of correcting the tendency to aberration arising from irregular form or density; and in order to investigate experimentally the nature of this action, I constructed an apparatus by which a cylindrical bullet could be put into extremely rapid rotation, and be then suspended in a manner which left it free to turn in any direction.

When thus suspended, the rotating bullet exhibited the same remarkable properties as are possessed by the revolving disc in the recently invented instrument called the "Gyroscope." When pressure was applied to either end of the axis, the movement which took place was not in the direction of the pressure, but at right angles to it. Thus a vertical pressure deflected the axis horizontally, while lateral pressure deflected it vertically. But the important point elicited was this, that the time required to produce these indirect movements became greater as the velocity was increased, and, consequently, that the amount of deflection produced in a given time by a given pressure, diminished as the rotation was accelerated. Now, all disturbing forces which operate upon a projectile during its flight, must necessarily be of very short continuance, and can therefore have but little influence in diverting the axis when thus stiffened by rapid rotation.

I also found that a cylindrical bullet with tapered extremities, was more easily deflected than one of equal weight with flat or merely rounded ends, because the mean diameter of the bullet, and consequently the mean velocity of rotation, were thereby diminished. So far, therefore, as accuracy of flight depends upon the rigidity of the axis, it would appear that the nearest practicable approach to a plain cylinder is the most desirable form for a projectile, but there are other considerations which modify this conclusion.

It is also to be observed, that since the rigidity of the axis (relatively to the magnitude of the projectile) depends upon the mean velocity of rotation, the inclination of the spiral grooves in a rifled gun should vary inversely with the diameter of the bore. Thus, if one turn in eight feet be assumed as sufficient for a rifled bore of one inch in diameter, one turn in forty-eight feet should be sufficient for a bore of six inches, provided the same form of projectile be used.

The forms of bullet which I actually tried with the gun were exceedingly numerous, and the materials used for these bullets was in all cases lead hardened by an intermixture of antimony and tin; and the weight varied from two to three and a half pounds.

In trying these various bullets, a number of each kind was fired against a vertical bank at a distance of 435 yards. The gun was constantly pointed at the same object, and the closeness of the bullet-holes to each other was taken as the criterion of accuracy, while the drop below the level of the aim furnished an indication of comparative range.

The conclusions arrived at from these and other experiments may be concisely stated as follows:—

1st.—A pointed form at the front end of the bullet is unfavourable to accuracy of flight, unless the cylindrical part of the bullet be of considerable length; but, on the other hand, a pointed or conoidal form behind, has the effect of increasing the accuracy attained. This may be explained upon the very probable supposition that the blast from the mouth of the gun, impinging upon the rear of the bullet, will operate more unfavourably upon a flat or hollow end than upon a rounded or conical one.

2nd.—Increase of length in the cylindrical part of a bullet always increases precision; but, when carried beyond a certain limit, lessens the initial velocity, even where the charge is proportionately augmented.

Digitized by Google

3rd.—Both range and accuracy were affected in an important degree by the manner in which the bullet fitted the contraction in the gun. When the fitting part was in front of the bullet, the pressure of the gas operating upon its sides compressed it, and the same effect was produced, though in a less degree, when the conical, or rounded end at the back, projected too far into the powder chamber.

These effects were rendered apparent by inspection of bullets recovered after firing, many of which were found in nearly the precise condition in which they quitted the gun.

The bullet ultimately selected is a little longer and heavier than those experimented with, and differs from the pointed bullet, in being longer in the cylindrical part and having a coned, instead of a rounded, end behind; and although its drop in a range of 435 yards is considerably more than that of several of the shorter bullets, yet there is little doubt it will excel them in range at higher elevations of the gun; because I have found that a pointed front only operates in sustaining the flight of the bullet when the range is long; and a high initial velocity, which materially lessens the drop in short distances, does not produce the same effect, in a corresponding degree, when the distance is increased.

Great improvements were effected in the accuracy of the firing, by modifying the shape of the projectile; but although the experiments were very protracted, I feel that they require to be further prolonged in order to arrive at the greatest attainable perfection in the form of the bullet.

The ranges at different elevations were not ascertained with the form of bullet ultimately adopted, but, with a three-pound pointed bullet and charges of twelve ounces of powder, they were as follows:—

Ranges with the rifled gun and three-pound bullets.

Elevation.	Range in Yards.	
½°	408	Measured to first graze upon a plane about five feet below the centre of the gun.
1°	770	
2°	1,112	
3°	1,500	
4°	1,840	
5°	2,056	
6°	2,300	
7°	2,600	

The powder used was a mixture of blasting and "double-seal" powder in equal proportions. The distances given are in most cases averages of several shots; but in some instances they were only approximately determined. When the gun had more elevation than 7° the bullets could only be fired out to sea, and the range could not be ascertained.

By way of comparison with these results, an extract is here given from the last edition of Sir H. Douglas's "Naval Gunnery," specifying the ranges obtained with a 68-pounder throwing shot with full charges, which ranges, it will be seen, are, upon the whole, no greater than those of the three-pound bullet fired from the rifled gun:—

Ranges with a 68-pounder.

Elevation.	Range in Yards.
½°	340
1°	833
2°	1,247
3°	1,558
4°	1,737
5°	2,035
6°	2,337
7°	2,440

In trying the initial velocity of the shot by means of a ballistic pendulum, I was enabled to observe its penetrating power. When fired with charges of 13 oz. of powder, a 3 lb. bullet passed through 2 feet 2 inches of hard elm timber, and flattened against a cast-iron block forming the back of the pendulum. The initial velocity was similar to that generally obtained with round shot fired with proportionate charges, viz. about 1,550 feet per second.

In the course of the experiments made with the gun, upwards of 500 rounds were fired; and ample opportunity was thus afforded of judging as to the durability of the parts affected by the loading at the breech. At first the fitting surfaces which closed the bore were of unhardened steel; but these soon failed, being cut away in numerous small channels by the ignited gases. The steel was then hardened; but instead of being rendered more durable, it yielded to the action of the powder more rapidly

Digitized by Google

than before. Conceiving, therefore, that the erosion was not a mechanical action, but a chemical effect of combustion, and that a metal which was a better conductor of heat than steel or iron would be less liable to burn on the surface, I was led to substitute copper as the material of the parts affected, and no further difficulty was experienced. The copper fittings applied for this purpose consist of two annular pieces, one of which is screwed into the breach end of the gun, and the other fixed upon the breech-piece. These fittings can very easily and quickly be repaired, when necessary, by means of a tool provided for that purpose, and can also be removed and replaced by others kept in readiness for use; and there is nothing to prevent these operations being performed by the gunners when on service, if they be previously instructed.

The advantages of loading at the breech may be stated as follows:—

1st.—It permits of a bullet being used of a larger diameter than the bore, by which means accuracy of fit is secured, and the material of the bullet is forced into the grooves of the bore.

2nd.—Any ignited matter remaining in the gun after firing may with ease and certainty be removed, or, if left in the gun, it will be thrust forward from the part where its presence would be dangerous, by the insertion of the succeeding bullet.

3rd.—In the arrangement which I have adopted, the perishable part of the gun, viz. the vent and its vicinity is comprised in the moveable breech-piece, which may be easily replaced when worn or otherwise injured.

4th.—A rifled gun loaded at the breech may be more rapidly fired than a rifled gun loaded at the muzzle, because the fouling of the bore presents no impediment to the insertion of the bullet when introduced from behind; but as compared with smooth-bored ordnance of the ordinary description, there is probably nothing to gain in point of quickness of firing.

The gun was remarkably free from tendency to become heated by firing, a fact which can only be explained upon the supposition that the heating of a cannon is occasioned, not by the contact of the flame, but by some molecular action of the metal, produced by the explosion, and more effectually resisted by wrought-iron than by cast-iron or bronze; but possibly the compound structure of this gun may also operate to deaden vibration, and prevent the evil in question.

It may, perhaps, be objected to this gun, that from the smallness of the bore, it cannot be applied for throwing shells as well as solid projectiles; but the fact is, these two purposes are incompatible with each other, unless both be imperfectly attained, for while the one necessarily requires a large bore, the other demands a small one; and it therefore seems preferable to have separate guns specially adapted for each application. As a civilian, I speak with diffidence upon the advantages which I believe the long range of this description of field-gun will afford in its military application; but I may be permitted to observe, that the incident which chiefly contributed to direct my attention to this subject still appears to furnish a forcible illustration of its importance. I allude to the memorable service rendered at Inkermann, by means of two 18-pounders, laboriously dragged from the batteries, and ultimately directed with great gallantry and success against the Russian Artillery, at a distance from which the numerous but lighter guns of the enemy could not effectually reply. Now, these two battery guns were but a clumsy substitute for light long-range guns, which would have rendered the same important service with more promptitude and ease, and could have operated at a greater distance from the enemy's fire. It is, perhaps, chiefly as "guns of position," commanding important points at great but ascertained distances, that these rifled guns would be valuable, because long range can only be made available where distance can be determined, which it cannot easily be in the rapid operations for which "field-pieces" are employed. It is, therefore, as adjuncts to, and not as substitutes for, the present description of field ordnance that I propose the adoption of these guns; and when fully brought to perfection, I believe they will furnish a most important addition to the artillery of an army.

With respect to the construction of heavy ordnance by the process of twisting wrought-iron bars into cylinders and combining them in the manner described, there appears to be no great difficulty in so doing, if proper apparatus be provided for the purpose. It would not, however, be advisable (except in peculiar cases) to apply the principle of loading at the breech except to guns of small dimensions, because in heavy ordnance the moveable parts would become too cumbrous to be conveniently handled."

The essential features of the Armstrong method of construction are:—

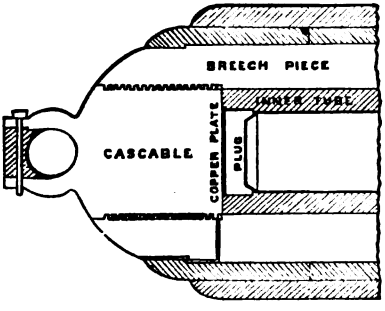
1st.—The disposal of the fibre of the metal round the bore by coiling, so as to resist the tangential strain, the welds running in the direction of the least strain as regards their separation.

2nd.—The employment of a breech piece, to support the bottom of the bore, with the fibre running lengthwise so as to resist longitudinal strain.

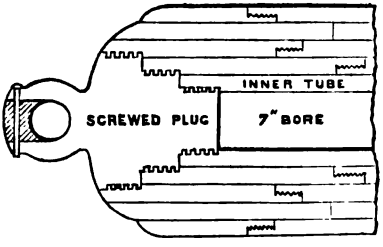
Digitized by Google

3rd.—The shrinking on the different portions, so that the exterior of the gun takes a due share of the strain. Mr. Whitworth's method of building up is as follows:—"The tube of the gun is made taper, being in the 5½ inch-bore gun 1 inch larger in diameter at the breech end than at the muzzle end; then a series of hoops are made, which are screwed together so as to form another tube, that is put on by hydraulic pressure, each layer is put on a little tighter than the succeeding one."—*Evidence Report on Ordnance.*

The method of closing the bore of a built-up gun is an important question. The inner tubes of some of the large M. L. ordnance lately constructed in the Royal Gun Factories, as well as those of some of Blakely's guns, have what are termed closed ends, that is, the tube is not bored through to the bottom; the solid end of the tube in service guns is supported by a cascable screwed into the breech-piece, and in some of them also by a shoulder in the breech-piece. Sir W. Armstrong, Mr. Whitworth and Major Palliser use open tubes and close them by a plug of wrought-iron or copper. The cascable in the Whitworth guns is not, like Armstrong's, cylindrical in form, but is shaped into two or more (screwed) cylinders, their respective diameters increasing from bore to breech.



Breech of Armstrong's 10·5 inch gun.



Breech of Whitworth's 7-inch gun.

In closing the bore of a M. L. or B. L. gun, one important principle should not be neglected, viz, that as the gas exerts an equal force in every direction the thickness of the metal should be as great, or nearly so, behind as over the charge. Inattention to this principle, or its sacrifice to other considerations, is a source of weakness in many B. L. guns. One advantage of an open end is, that the metal of the inner tube is relieved to some extent from longitudinal strain.

The relative cost of large ordnance made in different ways is approximately as follows:—

	£		
Cast-iron guns - - - - -	21	per ton.	
Armstrong built-up ditto - - -	100	,,	(lately £87.)
Krupp's steel ditto - - - - -	170	,,	
Gun metal ditto - - - - -	187	,,	

Bronze guns are valuable for recasting. Mr. Frazer has introduced modifications, by which it is said the cost of built-up ordnance will be much reduced, viz. to 40*l.* a ton with a coiled inner tube, and to 55*l.* a ton with a steel tube. Mr. Whitworth told the Committee on Ordnance that his 5½ inch gun weighing 4 tons, and made of homogeneous metal (soft steel) cost 700*l.* which is about 175*l.* per ton. The question of the relative advantages of breech and muzzle-loading ordnance has been frequently discussed. The subject appears very fairly put by Major C. H. Owen, Professor of Artillery, at Woolwich. He says:—"Various opinions are held as to the relative advantages of breech and muzzle-loading ordnance, but the latter would appear to be the best adapted to general service, as they are stronger for equal weights of metal and simpler in construction. The advantages of loading cannon at the breech are, that a projectile of larger diameter than the bore can be used, and its axis will consequently be stable; that the gun can be loaded when run up, the gunners being therefore less exposed, that the gun can be worked in a smaller space (than a M. L. piece); the clearing of the bore can be more readily effected, and any ignited sub-

Digitized by Google

stance left in the bore can be seen and removed, also there is no danger of the shot not being *home*. This plan, however, is attended with the following disadvantages, viz., that the construction is more complicated than that of a muzzle-loading piece; that if the gun be of large calibre, the breech-loading apparatus, when sufficiently strong and heavy, will be unwieldy; and that with the same weight of metal, the breech-loading is a weaker and less enduring construction than the muzzle-loading. On the other hand, a muzzle-loading gun has a simpler and stronger construction, but the gun detachments are more exposed than with a breech-loading gun, and if loaded carelessly, the shot may not be rammed *home*, in which case the metal of the gun may be fractured by the suddenly condensed gas."

On the Systems of Rifling.—Major Owen, R.A. one of our best authorities, writes:—"In what does a system of rifling consist. Essentially in the method of giving the rotatory motion to the projectile. This definition will not satisfy some inventors, who wish to claim a particular *twist* as a part of their *system of rifling*. It would, however, be quite as reasonable to claim a particular charge. The rotatory motion, as you all know, is given to prevent the projectile from turning over in flight; and the velocity of rotation required depends upon the form, length, and weight of the projectile, no matter what the system of rifling may be; in fact, the number of revolutions made by a shot $= \frac{\text{I. V.}}{\text{length of twist}}$, and therefore, with the same charge, the same twist must be obviously necessary.*

A twist, like a charge, may suit a particular rifled gun, but this is quite another thing. A *gaining twist* is advantageous, for, by employing it, the initial strain upon the gun is reduced, the rotatory motion not being given when the shot is set in motion, but gradually acquired as it moves down the bore. It is better to give rather more twist than is required under ordinary circumstances at the expense of a little extra strain; for should the twist be merely sufficient to impart the necessary rotatory motion with the service charge, the velocity of rotation will probably be too low with a reduced charge to keep the projectile steady in flight.†

The diameter of the bore has also been often mixed up with the system of rifling, with which it can have nothing whatever to do. As the diameter is decreased, so will the elongated projectile oppose a less surface (in proportion to its weight) to the resistance of the air, or that of the substance fired at; but, on the other hand, it will expose a less area to the force of the gas, and will therefore have a lower initial velocity; it will have less capacity as a shell; its cartridge must be elongated, thereby throwing the strain forward; the amount of powder that can be usefully employed will be less; and if the length of the bore be not increased, the expansion of the gas will be more limited. This question has been discussed, and should be thoroughly understood. In the table below the loss of initial velocity by decrease in the size of the bore is clearly shown:—

Ordnance.	Charge.	Projectile.		Initial Velocity.
		Weight.	Diameter.	
	lbs.	lbs.	inches.	
Britten's (32-pounder rifled) - -	5	50·36	6·24	1,209
Armstrong's 40-pounder - - -	- -	41·25	4·75	1,197
„ 3-grooved shunt - -	9	68·40	6·4	1,283
Whitworth's 70-pounder - - -	- -	68·56	{5·5 / 5·}	1,132
Armstrong's 70-pounder - - -	10	74·60	6·4	1,271
Whitworth's 70-pounder - - -	-	68·56	{·5 / 5·}	1,199

Mr. Whitworth and his admirers have constantly asserted that his small-bore gives a flatter trajectory than the larger bores chosen by Armstrong, Britten, and others. This is, however, not the case under all circumstances, and arose partly from the fact of the Whitworth guns first tried, being fired with charges of $\frac{1}{7}$th of the weight of the projectile, whereas the greater number of other rifled guns used charges of only $\frac{1}{8}$th or

* The Initial Velocity is very little effected by the system of rifling.

† This was particularly shown by the inaccurate practice of the 600-pounder, when fired with a small charge.

Digitized by Google

$\frac{1}{10}$th. Mr. Whitworth is quite right to use as large a charge as he can, but it must be taken into account in drawing comparisons. In practice from two rifled guns of different calibres, but firing projectiles of the same weight with equal charges, the large bore will give a lower trajectory; but as the projectile with the smaller diameter is less retarded, its trajectory will gradually become lower, as compared with the other, until beyond a certain range the small bore will give the lower trajectory. Small bores have found little favour on the continent, and it is for the authorities to demand either a large or a small bore as circumstances may require.

The following conditions are requisite in any rifled gun to ensure accuracy of fire:—a rotatory motion must be given to the projectile round an axis parallel to, or coincident with, that of the bore; and the velocity of rotation imparted to the projectile must be sufficient to counteract the pressure of air tending to turn the shot over or render it unsteady in flight.

Great numbers of rifled guns with projectiles to correspond have been proposed, but most of the systems of rifling that have been adopted by any service, or tried on the practice ground, may be divided into the following classes:—

(1) Muzzle or breech-loading guns, having projectiles of iron fitting the peculiar form of the bore mechanically.

(2) Muzzle-loading guns, with projectiles having soft metal studs or ribs to fit the grooves.

(3) Muzzle-loading guns, with projectiles having a soft metal envelope, coating, or cup, which is expanded by the gas in the bore.

(4) Breech-loading guns, with projectiles having a soft metal coating larger in diameter than the bore, but which is compressed by the gas to the form of the bore.

The effects of those guns, and consequently their relative values, will be best shown by extracting from the *Proceedings of the Royal Artillery Institution* some of the results as officially stated by the officers in charge of the experiments. The more important of the Targets have been selected, as representing the actual conditions of our ships at this time (1866), and of the power which can be brought to bear upon the armour-clad ships of an enemy.

Warrior Target.

This target was 10 ft. by 12 ft., consisted of three plates, made at the Park Head forge, all 4½ in. thick, and varying from 12 ft. by 3 ft. to 12 ft. by 3 ft. 4 in.

The Horsfall gun used weighed 24 tons 3 qrs. 2lbs., diameter of bore 13·014 in., diameter of shot 12·8 in. It was first fired at 200 yards range, with a solid cast-iron shot, weighing 279 lbs. and a charge of powder 74·40 lbs., which gave an initial velocity of 1,630 ft., reduced at 40 yards, to about 1,610 ft. per second.

The shot completely pierced the target through and through, making an irregular hole in the armour 2 feet square, and cracking but not buckling it.

From this and other similar experiments it appeared that the "Warrior" ship at 200 yards would be completely pierced by the Horsfall shot. A solid shot of annealed cast-iron weighing 285 lbs. was fired at the same target with the same charge as before, from a range of 800 yards. This grazed the ground 17 yards short, and struck the target in the junction of two plates, breaking a large hole about 2 feet square through the armour, and burying itself in the timber backing. This proves that at 800 yards the real "Warrior" would be severely injured, but the skin would would not be penetrated by an individual shot.

Mr. Whitworth made a series of experiments to prove the penetration of his projectiles. The shot and shell were fired from a 12-pounder breech-loader, a 70-pounder muzzle-loader and a 120-pounder muzzle-loader. Most of the shot and shell pierced the target; the following were the more remarkable results. A target was made in the form of a box, with the object of putting to the test Mr. Whitworth's boast that he could drive a shell through the side of an armour-clad ship, and make it burst between decks. The shell fired on this occasion, with an initial velocity of 1,275 feet, passed completely through the 4-inch armour plate and its oak backing, and exploded on the rear side of the box, the plate of which was indented 2½ in., bursting the box and blowing all six sides outwards.

A shell of homogeneous metal, weighing 127 lbs. with a bursting charge of 3 lbs. 8 oz. and without a fuze, was fired at the same range with a charge of 25 lbs. of powder, giving a terminal velocity of about 1,263 feet. This shell went completely through everything, much to the astonishment of every one present.

Some experiments were made on the "Warrior" target to prove the effect of steel shell fired from a 13·3" Armstrong M. L. wrought-iron shunt rifled gun at 2000 yards range. The initial velocity of the shell, with 51½ lbs. charge, is about 990 ft. and the striking velocity 940'.

Digitized by Google

Mean weight of shell empty	585 lbs.
Burster	24 „
Diameter of shell	13″24 „
Length { over all	23″
Length { of shell	19·75
Mean recoil	6ft. 1 in.

The third round struck about 10 yards short, and ricochetted on to centre of target, striking centre plate 4′ 2″ from left side; hole in plate 16″ × 13½″, centre plate started forward 6½″ at top and 4½″ at bottom on right side, and 3″ at top, and 0·5″ at bottom on left side, 11 armour-plate bolts started in centre plate and one in bottom plate. Upper plate blown off and lying at foot of target in front; all the bolts (except three) of this plate broken at nut—the three being drawn bodily out of the plate; bottom of upper plate, where shell entered, indented 1½″ in length of 1 ft. At the back ragged hole 4′ × 2′ 3″ between third and fourth ribs from right side; two ribs broken and forced out, second rib from right bulged, angle iron cracked; skin cracked and opened for length of 3′ below hole. Seventeen armour-plate holes, twenty-one rivets, and thirteen backing bolts broken. A great many splinters of iron, timber, bolt heads, &c., on raft. Shell on platform in rear of target broken up into four pieces.

The Bellerophon Target.

The part of the ship which was tested by the target is that situated between the main and lower decks, and not in the line of ports, the object being to test the strength of the general side of the ship. Special arrangements are made to strengthen the side in the vicinity of the ports, which will be few in number, as the "Bellerophon" carries a small number of very large guns. These few ports are strengthened by the introduction of additional iron to an extent which would not be practicable if the number of ports were large.

Each frame of the target was made of angle iron 10″ × 3½″ × ½″, and two angle irons 3½″ × 3½″ × ⅝″ rivetted together; to the double angle-irons of this frame the skin, which is composed of two thicknesses of ¾″ plating, making together 1½″, with a layer of painted canvas between, is riveted. On the outside of the skin plating, four horizontal angle-iron stringers are attached, two under the upper armour-plate 9½″ × 3½″ × ½″, the broad flange being square to the skin, and not reaching out to the armour by half an inch, the other two are placed behind the lower plate 10″ × 3½″ × ½″. The breadth of the broader flange being the same as the thickness of the backing, it reaches out to, and comes in contact with, the armour. Wood backing 10″ thick, is worked longitudinally on the skin plating and between the angle stringers, bolted with nut and screw bolts through the skin plating. The armour consists of two rolled plates, 6″ thick, manufactured at the Millwall works, weighing upwards of 9 tons each. The upper armour-plate is bolted with bolts 2½″ diameter and the lower plate with bolts 2¾″ diameter. In one half the target, divided vertically, the armour bolts have elastic washers and are clenched on single nuts. In the other half the bolts have common washers with double nuts, and bolts not clenched. In erecting the target, care was taken to support it behind with beam ends, &c., so that the actual condition of the proposed ship's side might be approximated to as closely as possible. All the portions of the target were carefully weighed, and the weight, as reported by the Admiralty overseer, was 389 lbs. per square foot.

The range was 200 yards, and the shot named below struck the target. The most decided effects were however produced by the guns named in the table on the next page:—

	lbs. weight.
From 10·5″ Armstrong rifled gun:—

Nature of Ordnance.	Weight in lbs. of Projectile.	Forms of Projectile.	Charge in lbs.	Remarks.
5½″ Whitworth gun.	69 Steel-shell.	*Cylindrical.* Bursting charge. 2 lbs. 6 oz.	12	Struck the lower plate 8″ from top and 5″ from right side, on a bolt; narrow crack on face of indent; armour-plate bolt driven in ½-inch; nut on bolt loose; one baulk of timber in backing split through.
10·5″ Armstrong gun.	150 Solid cast-iron shot.	*Spherical.* 10·36 diam.	35	Struck the upper plate 6″ from the lower edge on a bolt; plate cracked from bolt to bottom; crack 9″ long on face of indent; crack 10″ long and 1″ wide at 5″ from circumference of indent on right side; also two small cracks from bottom of plate at 5″ and 10″ respectively from left side of circumference; plate driven in 3½ at lower edge in length of 3′; plate started out 0·3″ at top on left side, and 0·2″ from lower plate. At the back a through armour-plate bolt driven out 2″; the heads of two backing bolts and one rivet broken off; one backing bolt driven out 1¼″; skin bulged slightly over area 1¼ square.
10·5″ Armstrong gun.	308 Solid cast-iron shot.	*Cylindrical.*	35	Struck the armour plate on the third bolt from the right side, lower row; plate driven in 2·1″ at bottom in a length of 5′; a crack 18″ long through a bolt hole at 2′ from impact plate started at 0·4″ from the backing on the right side for a length of 2′ at top. At the back one through armour-plate both driven out 2″, the heads of four rivets and one backing bolt broken off; vertical frame-piece cracked through and bent out slightly; beam-knee crushed; skin slightly bulged.
7″ Whitworth rifled-gun.	149·5 *Steel shell.*	*Cylindrical.* Bursting charge. 5 lbs. 8 oz. in flannel bag.	27	Struck lower plate; head of shell remained in hole; depth to nearest point of shell 9½ inches. At the back of the skin bulged at junction of skin plates, bottom plate 2″; upper plate 1″; rib bulged out 2″ at 2′ from ground; two deck knees separated from angle-iron 0·3; one armour-plate bolt, and three backing bolts broken; burst in backing.

Minotaur Target.

The armour is 5½ in. thick, the thickness of the teak backing is reduced from 18 in. as in the "Warrior" to 9 in., which is considered as equivalent to 1 in. of wrought iron. The target used July 7, 1862, constructed on those principles, presented a front of three armour-plates, one made by Messrs. Brown, of Sheffield, another by the Thames Iron Works, and the third by Messrs. Beale.

The guns used against this target were the 12-ton Armstrong muzzle-loading gun, throwing spherical 150 lb. cast-iron, and 162 lbs. wrought-iron shot, with 50 lb. charges of powder, the former having an initial velocity of 1750 ft. and the latter of about 1700 ft. per second; and a service 68-pounder throwing 67 lb. cast, and 71 lb. wrought-iron shot, with 16 lbs. of powder. The cast shot having an initial velocity of 1580 ft., the wrought-iron about 1530 ft. per second; all at 200 yards range. The first 150 lb. cast shot struck the Thames Iron Company's plate, and made a hole about a foot square through the armour, and bedded itself deep in the teak. The plate was buckled considerably, several bolts were started, two ribs cracked, the skin much bulged in, four bolts were broken, and a number of rivets.

Digitized by Google

The second 150 lb. shot struck the Sheffield plate, made a hole 13 in. by 12 in. in the armour, and sent pieces of the armour plate, shot, and teak, through a large irregular hole in the skin, the armour plate was buckled, three bolts broken, and other damage done. The third 150 lb. shot struck Messrs. Beale's plate, and did similar injury. These were the more important of the trials made upon this armour, proving that the powers of resistance in the "Minotaur" were inferior to those of the "Warrior."

The "Lord Warden" Target.

The target, 20 ft. by 9 in. represented the ordinary construction of a wooden ship, armour-plated, with the addition of a thick iron skin worked outside of the frame timbers of the ship. The following were the scantlings: frame timbers moulded 12½ in.; iron diagonal riders connecting the frame timbers, 6 in. by 1¼ in.; inner planking 8 in. thick; iron skin, 1¼ in. thick; outside planking, 8½ in. thick; rolled armour plates 20 ft. × 4 ft. 6 in. × 4·5 in. manufactured by the Millwall Company. The guns used were as follows:

	Weight. Tons.	cwt.	qrs.	lbs.
One 68-pounder smooth-bore muzzle-loading gun - -	0	95	0	0
One 9·22 in. muzzle-loading rifle gun 11 ft. long, 6 grooves	6	11	2	11
One 9·22 in. muzzle-loading rifled gun 13 ft. 3 in. long, 6 grooves - - - - - - - - - - -	12	2	2	0
One 10·5 in. muzzle-loading rifled gun 11 ft. 7 in. long, 10 grooves - - - - - - - - - - -	11	15	2	0
One 7 in. muzzle-loading rifled gun 10 ft. 9 in. long, 6 grooves - - - - - - - - - - -	6	13	3	0

The most remarkable effects were as follows:—

Nature of Ordnance.	Projectiles. Nature.	Weight in lbs.	Form and Diameter.	Charge in lbs.	Remarks.
10 ft. 5 in. Armstrong rifled gun.	Steel solid shot	168·25	*Spherical* 10·43	50	Struck upper plate 10 ft. from bottom, and 9′ 6″ from left side on a bolt, penetrated the armour-plate, making a hole in plate 11·5″ × 11, depth to surface of shot 12″, plate driven in 1′ 8″ at bottom; much damage was done at the back; two inner timbers were rent and splintered and thrust out, fragments projecting about 1′. Shot remained in hole apparently whole.
10 ft. 5 in. rifled gun.	Steel solid shot	301	*Cylindrical* 10·46	45	Struck at junction of plates 5′10″ from left of target; bolts at 15″, 13″, and 14″ from hole started 0·8″, 0·7″ and 0·4″ respectively; both plates laminated round the circumference of the hole, and two small cracks on front of lower plate from edge of hole. At the back, iron knee broken right off, and lower limb (4′ long with three bolts in it), driven 50′ to the rear. Area of damage 8′ × 4′, five or six plank bolts started and heads off; inner timbers rent in fragments and thrust out 1′ 6″; large splinters of wood scattered all around. Shot struck a large block of granite in rear, and broke itself into four pieces.

Digitized by Google

Some experiments were made to test the resistance of some rolled armour-plates made by Messrs. John Brown and Co., Sheffield.

The plates were of the following dimensions:—

One 13 ft. 4½ in., by 3 ft. 7 in., and 5½ in. thick.
One 12 „ 2¾ „ „ 3 „ 7½ „ „ 6½ „ „
One 11 „ 9 „ „ 3 „ 8½ „ „ 7½ „ „

They were secured by 2½ in. screw bolts, to the skin and frame of Mr. Samuda's old target; one half of each plate had a backing of from 7 in. to 9 in. of teak, and at the back of the other half, it was left hollow for an equal interval between the plates and the skin. India-rubber washers were used under the nuts.

The guns in position for trial, were:—

One 300-pounder Armstrong muzzle-loading shunt gun.
One 9-inch Lynall Thomas gun.
One 7-inch Whitworth rifle gun.
One 110-pounder Armstrong breech-loader.
One 68-pounder Service 95 cwt. gun.

All were fired at a range of 200 yards.

The first three shots (all cast-iron) were fired from the 68-pounder, one shot struck each plate and made indents 1½ in. deep in the 6½ in. and 7½ in. plates, and 2 in. deep in the 5½ in. plate.

These were followed by three shots from the 110-pounder, also of cast-iron; the indent upon the 5½ in. plate was 1·9 in. deep, that upon the 6½ in. was 2·05 in. deep, that upon the 7½ in. was 1·65 in. deep. There was scarcely any other effect visible.

The next shot was from the Armstrong 300-pounder, with a cylindrical steel shot weighing 301 lbs., and fired with a 45 lb. charge of powder. This shot had a velocity of 1295 ft. per second at 30 yards in front of the target, and struck the 7½ inch plate where it had the teak backing. The indent made was 6·2 in. deep, and its diameter about 12 in., or rather a circular piece of this diameter was driven in to a depth of 6·2 in., and nearly, if not quite, separated from the plate, which was of very good quality. There is, therefore, here a well defined measure of the full force of this shot. Besides this local effect, the target had evidently received a serious shake; one rib was cracked through and bent out, a number of small rivets were broken; the plate struck was buckled about 1½ in. and slightly cracked. The shot which rebounded from the target was set up about 2½ in., and was of excellent material.

A cylindrical steel shell, with a cast-iron head, made on a principle designed by Sir William Armstrong for the purpose of penetrating iron plates by directing the force of the explosion of the bursting charge *forward*, was next fired from the same gun. It weighed 288 lbs., had a bursting charge of 11 lbs., and was fired with a charge of 45 lbs. of powder, which gave at 25 yards in from the target, a velocity of 1320 ft. per second. It struck the 5½ in. plate on the part supported by the teak backing. It completely penetrated the armour-plate, leaving a hole about 14 in. in diameter, burst in the teak backing, tearing away the inner skin, and breaking a rib, and carried a shower of fragments and splinters in board. The teak was set on fire by the explosion, but easily extinguished; one bolt was broken, and other injuries done.

Altogether, for completeness of penetration and for the destructive effects which would have been produced both upon the ship and crew, this experiment carries with it great significance.

After this a cylindrical flat-headed homogeneous metal shell, weighing 148 lbs., with a bursting charge of 5 lbs 12 oz. was fired from the Whitworth 7 in. gun, with a charge of 25 lbs. of powder, which gave velocity at 30 yards in front of the target of 1265 ft. per second. This shell struck the 5½ in. plate near the hole made by the last Armstrong shell, punched out a clean cut hole about 9 in. in diameter, and burst in the teak backing; beyond blowing out some of the timber, it added very little indeed to the injury done by the Armstrong shell.

Lynall Thomas's 9-in. gun next missed the target with a round-headed solid steel shot weighing 327 lbs., fired with a charge of 50 lbs. of powder, which, at 546 ft. from the gun, gave a velocity of 1220 ft. per second.

The same gun next fired a wrought-iron solid flat-headed shot, weighing 302 lbs. with a charge of 50 lbs. of powder; the velocity of this shot was not obtained with certainty, it struck partly on the 6½ in. and partly on the 7½ in. armour; the greatest depth of impression on the latter plate was 6 in, and on the former 4 in. The 7½ in. plate was cracked through a bolt hole and round the indent, as was also the 6½ in. plate, but altogether the injury done was less than had been expected.

A hardened steel shot was next fired from the same gun; it weighed 330 lbs., was

Digitized by Google

round-headed, was fired with a charge of 50 lbs. of powder, which gave a velocity of 1220 ft. per second at 25 yards in front of the target. It struck close to the lower edge of the 7½ in. plate, and made an irregular indentation measuring about 1 ft. by 1 ft. 8 in., and 7 in. deep; two bolts were broken, one rib broken through, two others much bent, and the skin bulged in. The shot itself broke in half lengthways.

After this the 300-pounder Armstrong shunt gun fired a spherical wrought-iron solid shot, weighing 163 lbs. with a charge of 45 lbs., which at 30 yards in front of the target, gave a velocity of 1630 ft. per second. It struck the 7½ in. plate where it had no teak backing, and made an indent 3¾ in. deep, and 13 in. in diameter, with a crack on the face of the indent; the plate was considerably bulged in, and at the back it showed a large starred crack. The shot was flattened out to a diameter of 13 in.

The material of which these armour-plates was made proved itself to be of uniform and excellent quality.

The practical lessons to be learnt from such experiments seem to be these :—

1st. That guns are already in existence which can completely penetrate with shot the best 7½ in. armour that can be made, and which can, with shell, pierce the side of a ship built, as to frame, much more strongly than our best ship, and protected with our best 5½ in. armour.

2nd. That iron plates can now, with the improved manufacture of the country and the energy brought out by the occasion, be made of dimensions hitherto quite unattainable, and yet without losing anything in quality.

With the exception of America, other nations have done little or nothing in the manufacture of guns throwing projectiles over 100 lbs. in weight. The United States also boast the possession of two large rifled guns.

1st, an 8-inch gun, - - - 175 lb. projectile, 16 lbs. charge.
2nd, a 10 „ „ - - - 250 lb. „ 25 lbs. „

The following table gives the comparative values of the British muzzle-loading built-up ordnance, and the American smooth-bore ordnance.

All cast hollow except the 10 in. of 5·35 tons.

All shell guns except 10 in. 125-pounder.

20 in. gun only, at present experimental.

Solid shot are only to be fired from the 15 in. N. S. gun at iron-clad vessels, and then with 50 lbs.; 20 rounds may, however, be fired with 60 lbs.

The S. B. guns are formidable weapons, although they are merely cast-iron shell guns. Our guns being made of wrought-iron will not, on failure, break up like cast-iron or steel ordnance; and from their accuracy of fire, the capacity of their shells, and the power these latter have of maintaining a comparatively high velocity (in consequence of their elongated form) the British are in all probability greatly superior as weapons to the American guns.

Professor Major Owen, R.A., has ably dealt with the following important question.

"One of the most important questions at the present time is this: are monster guns required? Opinions are divided; but let us turn to facts, and see what has been done. I have endeavoured in the following table, to arrange some of the leading facts in order, so as to give an idea (necessarily a rough one) of the projectiles and charges necessary to actually penetrate certain structures at different ranges. I have not chosen the targets in preference to any others, but simply believing that they represent the average resistance offered by sea-going vessels, and also for convenience of comparison."

Target Penetrated by Steel Elongated Projectiles.

"It appears then, from what has been already accomplished, that there is at present no occasion to employ monster ordnance for the destruction of ordinary plated vessels."

"The guns we are now making, which will throw projectiles of 200 or 300 lbs. weight with charges of 45 lbs. are, if properly used, which no doubt they will be, quite sufficient for the purpose. Further than this, however, it is probable that few iron-plated sea-going vessels (now afloat) could withstand the fire of our rifled 7″ guns of 130 cwt., fired with 25 lbs. charges, at 800 or even 1,000 yards range; * for we must remember that in actual warfare, vessels are constantly subjected to a continual fire, and not merely a few blows delivered at certain intervals of time; and that a structure may thus be kept in a constant state of vibration by the repeated impacts of shots, and will offer less resistance than when time is allowed between the rounds, for the metal of the armour to resume its former condition of repose. We should also remember that the few plates upon which experiments are usually made, are in all probability of sounder construction than those produced in quantities for the plating of several vessels; also that when a ship has been for some time at sea, and may in addition have been in action, the armour (bolt plates and fastenings) will have been subjected to many shocks and strains, and will, therefore, have been considerably weakened."

SHELLS.—The hollow explosive projectiles that we call shells or bombs are a very old invention. Under the name of "coininges," they consisted of rudely formed globes of plate iron soldered together, filled with gunpowder and all sorts of miscellaneous "mitraille." These were thrown to short distances both from "pierriers" (a sort of mortar) and from catapultæ, as early as 1495 at Naples, 1590 at Padua, 1520 at Heilsberg, 1522 at Rhodes, and 1542 at Boulogne, Liège. About the middle of the 15th century bombs of cast iron seem to have come into use; an Englishman, named Malthus, learned the art of throwing them from the Dutch, and perfected the system for the French armies — being the first to throw shells in France, at the siege of La Mothe, in 1643. The diameter of the bomb seems at that time to have become fixed at 13 inches — the old Paris foot; and at this it remains (with very few exceptional cases) down to the present day.

A few attempts to increase the size and power of these projectiles have been made at different periods, but never with the practical skill necessary to success; for example, 18-inch shells were thrown by the French, at the siege of Tournay, in 1745; whereas, just a century before, the Swedes threw shells of 462 lbs. weight, and holding 40 lbs. of powder. The French, when they occupied Algiers in 1830, found numbers of old shells of nearly 900 lbs. in weight; and in almost every arsenal and fortress in Europe one or two old 16-inch and 18-inch shells are to be found. No attempt was made in modern days to realise the vast accession of power that such large shells confer, until the year 1832, when the "monster mortar," as it was then called, of 24 inches calibre, designed by Colonel Paixhans (the author of the Paixhans gun), was constructed by order of Baron Evain, the Belgian minister of war, and attempted to be used by the French at the siege of the citadel at Antwerp, but with the worst possible success. The mortar, a crude cylindrical mass of cast iron, sunk in a bed of timber weighing about 8 tons, and provided neither with adequate means for "laying" it, nor for charging it — the heavy shells weighing, when filled with 99 lbs. of powder, 1015 lbs. each — could with difficulty be fired three rounds in two hours, while the shells themselves were very badly proportioned.

One of these shells fell nearly close to the powder magazine, but did not explode; had it fallen upon the presumed bomb-proof arch of the magazine, containing 300,000 lbs. of powder, it would have pierced it, according to the opinion of all the military engineers present at the siege; and so closed the enterprise at a blow. The ill success of this mortar prevented for several years any attempt to develope bombs into their legitimate office — as the means of suddenly transferring mines into the body of fortified places — of a power adequate to act with decisive effect upon their works; although some years afterwards a 20-inch mortar was made in England for the Pacha of Egypt and proved at Woolwich.

But another circumstance still more tended to the neglect of large shells thrown by vertical fire. After repeated trials and many failures, it was found practicable to throw 10-inch (and since that even 13-inch) shells from cannon, or "shell guns," by projecting them nearly horizontally, or at such low angles that they should "ricochet" and roll along the ground before they burst; and, thus fired, it was soon seen that their destructive power *as against troops* was greater than if fired at angles approaching 45° of elevation from mortars. Paixhans and his school had pushed a

* The result of a recent experiment shows "that a structure such as the 'Warrior' can be penetrated at 200 yards range with elongated shot, and shot cast in chill when the form of the latter is elliptical, fired from a 7″ rifled gun with 25 charges;" and the report adds, "but it is probable that had the 7″ steel shot been elliptical-headed, instead of hemispherical-headed, penetration would also be effected at the longer range (1200 yards.")

Digitized by Google

good and useful invention beyond its proper limits, and had lost sight wholly of the all-important fact, that horizontal shell fire, powerful as it is against troops or shipping, is all but useless as an instrument of destruction to the works (the earthwork and masonry, &c.) of fortified places; for this end, weight and the penetrative power due to the velocity of descent in falling from a great height are indispensable.

A 13-inch shell, weighing about 180 lbs., is thrown, by a charge of 30 lbs. of powder, barely 4700 yards. While, with not much more than double this amount of powder, the 36-inch shell, of more than 14 times its weight, can be thrown 2650 yards, or much more than half the distance.

The explosive power, it is obvious, is approximately proportionate to the weight of powder; but, by calculations, of which the result only can here be given, Mr. Mallet has shown that the total power of demolition—that is to say, the absolute amount of damage done in throwing down buildings, walls, &c. &c.—by one 39-inch shell is 1600 times that possible to be done by one 13-inch shell; and that an object which a 13-inch shell could just overturn at one yard from its centre, will be overthrown by the 36-inch shell at 40 yards' distance.

A 13-inch shell penetrates, on falling upon compact earth, about 2½ feet. The Antwerp shell penetrated 7 feet. The 36-inch shell penetrated 16 to 18 feet. The funnel-shaped cavity, or "crater," of earth blown out by the explosion of a buried shell, is always a similar figure, called a "paraboloid;" its diameter at the surface, produced by the 13-inch shell, is about 7 feet, and by the 36-inch shell about 40 feet.

No bomb-proof arch (so called) now exists in Europe capable of resisting the tremendous fall of such masses, and the terrible powers of their explosion when 480 lbs. of powder, fired to the very best advantage, puts in motion the fragments of more than a ton of iron. No precautions are possible in a fortress; no splinter-proof, no ordinary vaulting, perhaps no casemate, exists capable of resisting their fall and explosion. Such a shell would sink the largest ship or floating battery.

A single 36-inch shell in flight costs 25*l.*, and a single 13-inch 2*l.* 2*s.*, yet the former is the *cheaper* projectile; for, according to Mr. Mallet's calculations, to transfer to the point of effect the same weight of bursting powder, we must give—

ARTIFICIAL STONE. See STONE, ARTIFICIAL.

ARUM VULGARE. *A. maculatum; The Wake-robin; Lords and Ladies.* In the island of Portland a kind of arrow root was prepared from this plant. See ARROW ROOT.

ASBESTOS, from ἄσβεστος, *unconsumable.* (*Asbeste*, Fr.; *Asbest*, Germ.) When the fibres of the fibrous varieties of amphibole are so slender as to be flexible, it is called asbestos, or amianthus. It is found in Piedmont, Savoy, Salzburg, the Tyrol, Dauphiné, Hungary, Silesia; also in Corsica so abundantly as to have been made use of by Dolomieu for packing minerals; in the United States, St. Kevern in Cornwall, in Aberdeenshire, in some of the islands north of Scotland, and Greenland. Asbestus was manufactured into cloth by the ancients, who were well acquainted with its incombustibility. This cloth was used for napkins, which could be cleansed by throwing them into the fire; it was also used as the wick for lamps in the ancient temples; and it is now used for the same purpose by the natives of Greenland. It has been proposed to make paper of this fibrous substance, for the preservation of important matters. An Italian, Chevalier Aldini, constructed pieces of dress which are incombustible. Those for the body, arms, and legs were formed out of strong cloth steeped in a solution of alum; while those for the head, hands, and feet were made of cloth of asbestus. A piece of ancient asbestus cloth, preserved in the Vatican, appears to have been formed by mixing asbestus with other fibrous substances; but M. Aldini has executed a piece of nearly the same size, which is superior to it, as it contains no foreign substance. The fibres were prevented from breaking by the action of steam. The cloth is made loose in its fabric, and the threads are about the fiftieth of an inch in diameter. The Society of Encouragement, of Paris, has proposed a prize for the improvement of asbestus cloth. The use of it was publicly exhibited in London in 1858.

Common Asbestos is found in fibres of a dull greenish colour and of a somewhat pearly lustre. In the Serpentine formations at the Lizard Point, in Cornwall, it is common. Dr. M'Culloch found it in the limestone of Glentilt in a pasty state, but it hardened upon exposure.

Mountain Leather, or *Mountain Paper*, is not in parallel fibres like the preceding, but the fibres are interwoven. The thinner pieces bear the latter name. Wanlock Head is the best known locality in this country.

Elastic Asbestos, or *Mountain Cork*, floats on water. It has, like the preceding, an interlaced fibrous texture. It varies in colour, being white, grey, yellow, or brown. In appearance and feel it is not unlike common cork, and it has a certain degree of elasticity, hence its name.

Mountain Wood, or *Ligniform Asbestos*. This variety is usually massive, and of a brown colour, having much the appearance of wood. It is found in several localities in Scotland.

ASH. (*Fraxinus excelsa.*) Ash is superior to any other British wood for its toughness and elasticity. It is therefore used for the frames of machines, for agricultural implements, and the felloes of wheels. This wood is split into pieces for the springs of bleachers' rubbing boards. Handspikes, hammer handles, rails for chairs, &c., are made from the ash. All these and similar works are much stronger when they follow the natural fibre of the wood. Hoops are also frequently made of the young branches of the ash. Rankine gives its tenacity as 17,000, and its modulus of elasticity, or resistance to stretching, as 1,600,000.

ASHES. In commerce, the word ashes is applied to the ashes of vegetable substances from which the alkalis are obtained, as KELP, BARILLA, &c. (*which see.*)

It is the popular name of the vegetable alkali, potash, in an impure state, as procured from the ashes of plants by lixiviation and evaporation. The plants which yield the greatest quantity of potash are wormwood and furmitory. See POTASH, PEARLASH, and, for the mode of determining the value of ashes, ALKALIMETRY.

Commercially ashes are divided into soap ashes, wood ashes, (*vedasse*, Fr.; *waidasche*, Germ.), and weed ashes. Our importations have been as follows:—

Imported.	Alkali, viz. Ashes, Pearl and Pot. Cwts.	Other sorts. Tons.
1859	155,663	917
1860	141,087	616

ASHES OF PLANTS. The ashes of all species of woods and weeds are found to contain some alkali, hence it is that the residuary matter, after the combustion of any vegetable matter, acts as a stimulant to vegetable growth.

The following analyses of the ashes of plants have been selected from the tables which have been published, by Messrs. Thomas Way and G. Ogston, in the "Journal of the Agricultural Society":—

* Griepenkerl. † Griepenkerl. ‡ A. Müller. § Way. ‖ Hubert. ¶ Way.

The large amount of silica found in the grasses, constituting, as it does, their outer coating, cannot fail to be noticed. The variations in the quantities of phosphoric acid are instructive.

ASHLAR. When stones are worked in regular beds and joints, and are dressed for facing work, they are called ashlar. The stone used as ashlar is called *ashlaring*, when in thin slabs, and made to serve merely as a case to the regular body of the wall.

ASPARAGINE. ($C^8\ H^8\ N^2\ O^6 + 2$ Aq. *Syn.* Asparamide, malamide, altheine. A beautifully crystallised substance, first found in asparagus juice, by Vauquelin and Robiquet, in 1805. It not only exists in a great number of vegetables, but some which do not contain it naturally may be made to afford it by being grown in dark damp cellars. Many plants normally containing only small quantities of it may be made to yield more by being allowed to germinate in that manner. Among the vegetables from which it can be directly obtained may be mentioned the following:—*Althæa officinalis, Asparagus acutifolius, A. off., Atropa belladonna, Convallaria majalis, C. multiflora, Cynodon dactylon, Glycyrrhiza glabra, Lactuca sativa, Ornithogalum*

Digitized by Google

caudatum, *Paris quadrifolia*, *Robinia pseudacacia*, *Solanum tuberosum*, and *Symphytum off.* The following list contains the names of some plants normally containing no asparagine, but yielding it when allowed to germinate in darkness in damp cellars :—*Colutea arborescens*, *Cytisus laburnum*, *Ervum lens*, *Genista juncea*, *Hedysarum onobrychis*, *Lathyrus odoratus*, *L. latifolius*, *Phaseolus vulgaris*, *Pisum sativum*, *Trifolium pratense*, *Vicia Faba*, and *V. sativa.*

Preparation.—Perhaps the most convenient and economical mode of procuring asparagine is from the etiolated (blanched) shoots of vetches. When they have acquired a length of two inches—which, under favourable circumstances, will be in about three weeks—they are to be crushed, and the juice pressed out. The quantity yielded will be rather less than three-fourths of the weight of the plant. It is then to be boiled for a short time, to coagulate the vegetable albumen, and strained. This clarified fluid is to be evaporated until almost syrupy, and put aside to crystallise. The product is at first brown, but by washing with cold water, afterwards dissolving in boiling water, and subsequent crystallisation, it may be obtained pure. If, previous to putting the hot fluid aside to crystallise, a little pure animal charcoal be added, and the whole be digested a short time, and then filtered, the crystals will be obtained brilliantly white at one operation. Some chemists advise the germination to be allowed to go much further than was mentioned above, so that the shoots may be as long as 15 inches. The crystals obtained by the process given have the formula $C^8\ H^8\ N^2\ O^6 + 2$ Aq., but the water is expelled at 212°. Asparagine possesses the peculiarity of behaving like a base towards strong oxides and like an acid towards bases. The crystals obtained by the method given contain, in the 100 parts, carbon 32·00, hydrogen 6·67, nitrogen 18·67, oxygen 42·66. Dried at 212°, it has the following composition: carbon 36·36, hydrogen 6·06, nitrogen 21·21, oxygen 36·37.—C. G. W.

ASPHALTENE. A product obtained from asphaltum by volatilising the oily and volatile product *petrolene.*

ASPHALTIC MASTIC, used in Paris for large works, is brought down the Rhone from Pyrimont, near Lyssell. It is composed of nearly pure carbonate of lime, and about 9 or 10 per cent. of bitumen.

When in a state of powder it is mixed with about 7 per cent. of bitumen or mineral pitch, found near the same spot. The powdered asphalt is mixed with the bitumen in a melted state along with clean gravel, and consistency is given to pour it into moulds. Sulphur added to about 1 per cent. makes it very brittle. The asphalt is ductile, and has elasticity to enable it, with the small stones sifted upon it, to resist ordinary wear. Walls having cracked, and parts having fallen, the asphalte has been seen to stretch and not crack. It has been regarded as a sort of mineral leather. The sun and rain do not appear to affect it; and it answers for *abattoirs* and barracks, keeps vermin down, and is uninjured by the kicking of horses.

ASPHALT OIL. An oil obtained from asphaltum by dry distillation.

ASPHALTUM. (*Bitume* or *Asphalte*, Fr. ; *Asphalt*, Germ.) Mineral Pitch; so called from the lake Asphaltites; a variety of bitumen, arising from one of the many peculiar changes of vegetable matter. Asphaltum, in common with other varieties of bitumen, is a form of hydrocarbon produced in the interior of the earth by the transformation of carbonaceous matter, like all combustible bodies of the same class. Composition $C^6\ H^3$. It is a solid black or brownish-black substance, possessing a bright conchoidal fracture. It fuses at 212° F., burning with a brilliant flame and emitting a bituminous odour. Specific gravity=1 to 1·2. Asphaltum is insoluble in alcohol, but soluble in about five times its weight of naphtha. See BITUMEN, JEWS' PITCH, NAPHTHA.

This solid shining bitumen, of a deep black colour when broken, is found in many parts of Egypt. A thin piece appears of a reddish colour when held to the light; when cold, it has no odour; by a moderate heat or by friction, the odour is slightly fully heated, it liquifies, swells, and burns with a thick smoke; the odour given is acrid, strong, and disagreeable.

In the arts, asphaltum is used as a component of japan varnish. It is likewise employed as a cement for lining cisterns, and for pavements, as a substitute for flag stones.—H. W. B.

ASPHALTUM, GAS TAR, or ARTIFICIAL. When, with the thick pitchy residue, obtained by evaporating off the more volatile portions of gas, tar, sand, chalk or lime are mixed, it is called artificial asphaltum. The mineral substances are strongly heated to expel all moisture, and then added to the pitch while in the melted state. This is used for pavements, for lining tanks, &c.

The following quantities of Asphaltum, or *Bitumen Judaicum*, were *imported* into

Great Britain—in 1855, 1674 tons; in 1856, 2707 tons, of which 2573 tons were from France.

ASSAFŒTIDA. (*Assus*, dried; *fœtidus*, fetid). A fetid gum resin obtained from the root of the *Narthex Assafœtida*.

ASSAY and ASSAYING. (*Coupellation*, Fr.; *Abtreiben auf der capelle*, Germ.) This is the process by which the quality of gold and silver bullion, coin, plate, or trinkets is ascertained with precision.

The art of assaying gold and silver *by the cupel* is founded upon the feeble affinity which these metals have for oxygen, in comparison with copper, tin, and the other cheaper metals; and on the tendency which the latter metals have to oxidise rapidly in contact with lead at a high temperature, and sink with it into any porous earthy vessel in a thin glassy or vitriform state. The porous vessel may be made either of wood-ashes, freed from their soluble matter by washing with water; or, preferably, of burned bones reduced to a fine powder.

Quantity of Lead to be employed for Alloys (M. D'Arcet).

Alloy.		Lead for 1 of Alloy.	Ratio of the Copper to the Lead.
Silver.	Copper.		
1000	0	$\frac{3}{10}$	0

200	800	16—17	1 : 20
100	900	16—17	1 : 17·8
0	1000	16—17	1 : 16

Bismuth may be used as a substitute for lead in cupellation; two parts of it being nearly equivalent to three of lead. But its higher price will prevent its general introduction among assay masters.

We begin this assay process by weighing, in a delicate balance, a certain weight of the metallic alloy; a gramme (= 15·432 gr.) is usually taken in France, and 12 grains in this country. This weight is wrapped up in a slip of lead foil or paper, should it consist of several fragments. This small parcel, thus enveloped, is then laid in a watch glass or a capsule of copper, and there is added to it the proportion of lead suited to the quality of alloy to be assayed; there being less lead, the finer the silver is presumed to be. Those who are much in the habit of cupellation can make good guesses in this way; though it is still guess-work, and often leads to considerable error, for if too much lead be used for the proportion of baser metal present, a portion of the silver is wasted; but if too little, then the whole of the copper, &c. is not carried off, and the button of fine silver remains more or less impure. The most expert and experienced assayer by the cupel produces merely a series of approximate conjectural results, which fall short of chemical demonstration and certainty in every instance. The lead must be, in all cases, entirely free from silver, being such as has been revived from pure litharge; otherwise errors of the most serious kind would be occasioned in the assays.

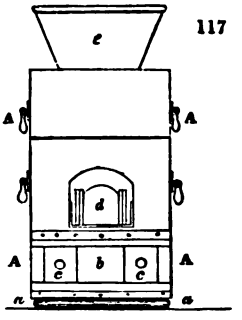
The best cupels weigh 12½ grammes, or 193 grains. The cupels allow the fused oxides to flow through them as through a fine sieve, but are impermeable to the particles of metals; and thus the former pass readily down into their substance, while the latter remain upon their surface; a phenomenon owing to the circumstance of the glassy oxides moistening, as it were, the bone-ash powder, whereas the metals can contract no adherence with it. Hence also the liquid metals preserve a hemispherical shape in the cupels, as quicksilver does in a cup of glass, while the fused oxide spreads over, and penetrates their substance, like water. A cupel may be regarded, in some measure, as a filter permeable only to certain liquids.

If we put into a cupel, therefore, two metals, of which the one is unalterable in the air, the other susceptible of oxidisement, and of producing a very fusible oxide, it is obvious that, by exposing both to a proper degree of heat, we shall succeed in separating them. We should also succeed, though the oxide were infusible, by placing it in contact with another one, which may render it fusible. In both cases, however,

Digitized by Google

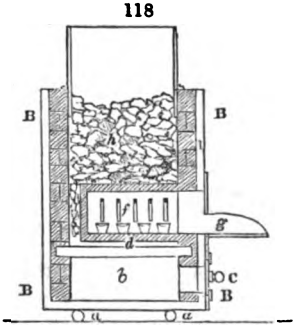
the metal from which we wish to part the oxides must not be volatile; it should also melt, and form a button at the heat of cupellation; for otherwise it would continue disseminated, attached to the portion of oxide spread over the cupel, and incapable of being collected.

The furnace and implements used for assaying in the Royal Mint and Goldsmiths' Hall, in the city of London, are the following:—



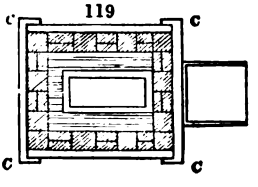
A A A A (*fig.* 117) is a front elevation of an assay furnace; *a a*, a view of one of the two iron rollers on which the furnace rests, and by means of which it is moved forward or backward; *b*, the ash-pit; *c c* are the ash-pit dampers, which are moved in a horizontal direction towards each other for regulating the draught of the furnace; *d*, the door, or opening, by which the cupels and assays are introduced into the muffle; *e*, a movable funnel or chimney by which the draught of the furnace is increased.

B B B B (*fig.* 118) is a perpendicular section of *fig.* 117; *a a*, end view of the rollers; *b*, the ash-pit; *c*, one of the ash-pit dampers; *d*, the grate, over which is the plate upon which the muffle rests, and which is covered with loam nearly one inch thick; *f*, the muffle in section, representing the situation of the cupels; *g*, the mouth-plate, and upon it are laid pieces of charcoal, which, during the process, are ignited, and heat the air that is allowed to pass over the cupels, as will be more fully explained in the sequel; *h*, the interior of the furnace, exhibiting the fuel.



The total height of the furnace is 2 feet 6¼ inches; from the bottom to the grate, 6 inches; the grate, muffle, plate, and bed of loam, with which it is covered, 3 inches; from the upper surface of the grate to the commencement of the funnel *e*, *fig.* 117, 21¼ inches; the funnel *e*, 6 inches. The square of the furnace which receives the muffle and fuel is 11¾ inches by 15 inches. The external sides of the furnace are made of plates of wrought iron, and are lined with a 2-inch fire-brick.

C C C C (*fig.* 119) is a horizontal section of the furnace over the grate, showing the width of the mouth-piece, or plate of wrought iron, which is 6 inches, and the opening which receives the muffle-plate.



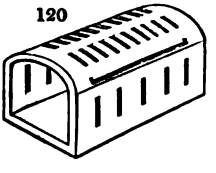


Fig. 120 represents the muffle or pot, which is 12 inches long, 6 inches broad inside; in the clear 6¾: in height 4¼ inside measure, and nearly 5¼ in the clear.

Fig. 121, the muffle-plate, which is of the same size as the bottom of the muffle.

Fig. 122 is a representation of the sliding-door of the mouth-plate, as shown at *d*, in *fig.* 117.

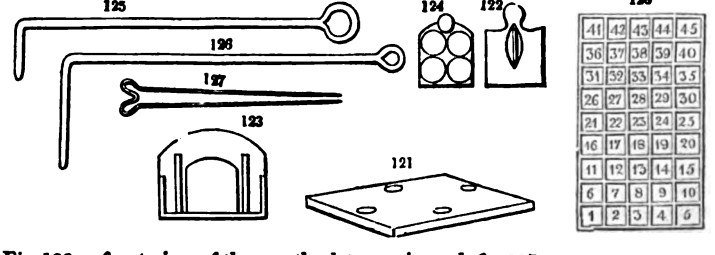

Fig. 123, a front view of the mouth-plate or piece, *d*, *fig.* 117.

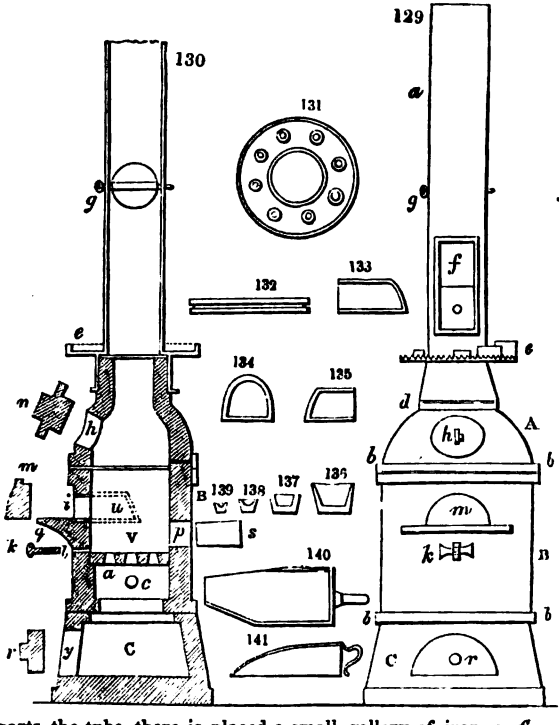
Fig 125, the teaser for cleaning the grate.

Fig. 126, a larger teaser, which is introduced at the top of the furnace, for keeping a complete supply of charcoal around the muffle.

Fig. 127, the tongs used for charging the assays into the cups.

Fig. 128 represents a board of wood used as a register, and is divided into 45 equal compartments, upon which the assays are placed previously to their being introduced into the furnace. When the operation is performed, the cupels are placed in the furnace in situations corresponding to these assays on the board. By this means all confusion is avoided, and without this regularity it would be impossible to preserve the accuracy which the delicate operations of the assayer require.

We now proceed to a description of a small assay furnace invented by Messrs. Anfrye and D'Arcet, of Paris. They term it, *le petit Fourneau à Coupelle. Fig.* 129 represents this furnace, and it is composed of a chimney or pipe or wrought iron, *a*, and of the furnace, B. It is 17½ inches high, and 7½ inches wide. The furnace is formed of three pieces; of a dome, A; the body of the furnace, B; and the ash pit, C, which is used as the base of the furnace, *figs.* 129 and 130. The principal piece, or body of the furnace, B, has the form of a hollow tower, or of a hollow cylinder, flattened equally at the two opposite sides parallel to the axis, in such a manner that the horizontal section is elliptical. The foot which supports it is a hollow truncated cone, flattened in like manner upon the two opposite sides, and having consequently for its basis two ellipses of different diameters: the smallest ought to be equal to that of the furnace, so that the bottom of the latter may exactly fit it. The dome, which forms an arch above the furnace, has also its base elliptical, whilst that of the superior orifice, by which the smoke goes out, preserves the cylindrical form. The tube of wrought iron is 18 inches long, and 2½ inches in diameter, having one of its ends a little enlarged, and slightly conical, that it may be exactly fitted or jointed upon the upper part of the furnace dome, *d* (*fig.* 129). At the union of the conical and cylindrical parts the tube, there is placed a small gallery of iron, *e*, *figs.* 129, 130. (See also a plan of it, *fig.* 131.) This gallery is both ingenious and useful. Upon it are placed the cupels, which are thus annealed during the ordinary work of the furnace, that they may be introduced into the muffle when it is brought into its proper degree of heat. A little above this gallery is a door, *f*, by which, if thought proper, the charcoal could be introduced into the furnace; above that there is placed at *g* a throttle valve, which is used for regulating the draught of the furnace at pleasure. Messrs. Anfrye and D'Arcet say, that, to give the furnace the necessary degree of heat so as to work the assays of gold, the tube must be about 18 inches above the gallery for annealing or heating the cupels. The circular opening in the dome, *h* (*fig.* 129, and as seen in section *fig.* 130), is used to introduce the charcoal into the furnace: it is also used to inspect the interior of the furnace, and to arrange the charcoal round the muffle. This opening is kept shut during the working of the furnace, with the mouth-piece, of which the face is seen at *n*, *fig.* 130.



Digitized by Google

The section of the furnace, *fig.* 130, presents several openings, the principal of which is that of the muffle; it is placed at *i*; it is shut with the semicircular door *m*, *fig.* 129, and seen in the section *m*, *fig.* 130. In front of this opening, is the table or shelf upon which the door of the muffle is made to advance or recede. The letter *q*, *fig.* 130, shows the face, side, and cross section of the shelf, which makes part of the furnace. Immediately under the shelf is a horizontal slit, *l*, which is pierced at the level of the upper part of the grate, and used for the introduction of a slender rod of iron, that the grate may be easily kept clean. This opening is shut at pleasure, by the wedge represented at *k*, *figs.* 129 and 130.

Upon the back of the furnace is a horizontal slit, *p*, *fig.* 130, which supports the fire brick, *s*, and upon which the end of the muffle, if necessary, may rest; *u*, *fig.* 130, is the opening in the furnace where the muffle is placed.

The plan of the grate of the furnace is an ellipse: *fig.* 132 is a horizontal view of it. The dimensions of that ellipsis determine the general form of the furnace, and thickness of the grate. To give strength and solidity to the grate, it is encircled by a bar or hoop of iron. There is a groove in which the hoop of iron is fixed. The holes of the grate are truncated cones, having the greater base below, that the ashes may more easily fall into the ash-pit. The letter *v*, *fig.* 130, shows the form of these holes. The grate is supported by a small bank or shelf, making part of the furnace, as seen at *a*, *fig.* 130.

The ash-pit, c, has an opening, *y*, in front, *fig.* 130; and is shut when necessary by the mouth-piece, *r*, *figs.* 129 and 130.

To give strength and solidity to the furnace, it is bound with hoops of iron, at *b b b b*, *fig.* 129.

Figs. 133, 134, 135, are views of the muffle.

Fig. 136 is a view of a crucible for annealing gold.

Figs. 137, 138, 139, are cupels of various sizes, to be used in the furnace. They are the same as those used by assayers in their ordinary furnaces.

Figs. 140 and 141 are views of the hand-shovels, used for filling the furnace with charcoal; they should be made of such size and form as to fit the opening *h*, in *figs.* 129 and 130.

The smaller pincers or tongs, by which the assays are charged into the cupels, and by which the latter are withdrawn from the furnace, as well as the teaser for cleansing the grate of the furnace, are similar to those used at the British Mint.

In the furnace of the Mint above described, the number of assays that can be made at one time is 45. The same number of cupels is put into the muffle. The furnace is then filled with charcoal to the top, and upon this are laid a few pieces already ignited. In the course of three hours, a little more or less according to circumstances, the whole is ignited; during which period the muffle, which is made of fire-clay, is gradually heated to redness, and is prevented from cracking, which a less regular or more sudden increase of temperature would not fail doing: the cupels, also, become properly annealed. All moisture being dispelled, they are in a fit state to receive the piece of silver or gold to be assayed.

The greater care that is exercised in this operation, the less liable is the assayer to accidents from the breaking of the muffle; which it is both expensive and troublesome to fit properly into the furnace.

The cupels used in the assay process are made of the ashes of burnt bones (phosphate of lime). In the Royal Mint, the cores of ox-horn are selected for this purpose; and the ashes produced are about four times the expense of the bone-ash used in the process of cupellation on a large scale. So much depends upon the accuracy of an assay of gold or silver, where a mass of 15 lbs. troy in the first, and 60 lbs. troy in the second instance, is determined by the analysis of a portion not exceeding 20 troy grains, that every precaution which the longest experience has suggested is used to obtain an accurate result. Hence the attention paid to the selection of the most proper materials for making the cupels.

The cupels are formed in a circular mould made of cast steel, very nicely turned, by which means they are easily freed from the mould when struck. The bone-ash is used moistened with a quantity of water, sufficient to make the particles adhere firmly together. The circular mould is filled, and pressed level with its surface; after which, a pestle or rammer, having its end nicely turned, of a globular or convex shape, and of a size equal to the degree of concavity wished to be made in the cupel for the reception of the assay, is placed upon the ashes in the mould, and struck with a hammer until the cupel is properly formed. These cupels are allowed to dry in the air for some time before they are used. If the weather is fine, a fortnight will be sufficient.

An assay may prove defective for several reasons. Sometimes the button or bead

Digitized by Google

sends forth crystalline vegetations on its surface with such force as to make one suppose a portion of the silver may be thrown out of the cupel, technically called "*spitting.*" When the surface of the bead is dull and flat, the assay is considered to have been too hot, and it indicates a loss of silver in fumes. When the tint of the bead is not uniform, when its inferior surface is bubbly, when yellow scales of oxide of lead remain on the bottom of the cupel, and the bead adheres strongly to it,—by these signs it is judged that the assay has been too cold, and that the silver retains some lead.

Lastly, the assay is thought to be good if the bead is of a round form, if its upper surface is brilliant, if its lower surface is granular and of a dead white, and if it separates readily from the cupel.

After the lead is put into the cupel, it gets immediately covered with a coat of oxide, which resists the admission of the silver to be assayed into the melted metal; so that the alloy cannot form. When a bit of silver is laid on a lead bath in this predicamant, we see it swim about for a long time without dissolving. In order to avoid this result, the silver is wrapped up in a bit of paper; and the carburetted hydrogen generated by its combustion reduces the film of the lead oxide, gives the bath immediately a bright metallic lustre, and enables the two metals readily to combine.

As the heat rises, the oxide of lead flows round about over the surface, till it is absorbed by the cupel. When the lead is wasted to a certain degree, a very thin film of it only remains on the silver, which causes the iridescent appearance like the colours of soap-bubbles—a phenomenon called, by the old chemists, fulguration.

When the cupel cools in the progress of the assay, the oxygenation of the lead ceases; and, instead of a very liquid vitreous oxide, an imperfectly melted oxide is formed, which the cupel cannot absorb. To correct a cold assay, the temperature of the furnace ought to be raised, and pieces of paper put into the cupel, till the oxide of lead which adheres to it be reduced. On keeping up the heat, the assay will resume its ordinary train.

Pure silver almost always vegetates. Some traces of copper destroy this property, which is obviously due to the oxygen which the silver can absorb while it is in fusion, and which is disengaged the moment it solidifies. An excess of lead, by removing all the copper at an early stage, tends to cause the vegetation.

The brightening is caused by the heat evolved when the button passes from the liquid to the solid state. Many other substances present the same phenomenon.

In the above operation it is necessary to employ lead which is very pure, or at least free from silver. This is called *poor lead.* I have found the lead reduced from Pattison's "oxychloride" to be more free from silver than any that I could obtain by any other means; the lead reduced from the litharge of commerce usually contains from 10 to 15 dwts. of silver per ton.

It has been observed at all times, that the oxide of lead carries off with it, into the cupel, a little silver in the state of an oxide. This effect becomes less, or even disappears, when there is some copper remaining; and the more copper, the less chance there is of any silver being lost. The loss of silver increases, on the other hand, with the dose of lead. Hence the reason why it is so important to proportion the lead with a precision which, at first sight, would appear to be superfluous. Hence, also, the reason of the attempts which have, of late years, been made to change the whole system of silver assays, and to have recourse to a method exempt from the above causes of error.

M. D'Arcet, charged by the Commission of the Mint in Paris to examine into the justice of the reclamations made by the French silversmiths against the public assays, ascertained that they were well founded; and that the results of cupellation gave for the alloys between 897 and 903 thousandths (the limits of their standard coin) an inferior standard, by from 4 to 5 thousandth parts, from the standard or title which should result from the absolute or actual alloy.

The mode of assay shows, in fact, that an ingot experimentally composed of 900 thousandths of fine silver and 100 thousandths of copper, appears, by cupellation, to be only, at the utmost, 896 or 897 thousandths; whereas fine silver of 1000 thousandths comes out nearly of its real standard. Consequently, a director of the Mint who should compound his alloy with fine silver would be obliged to employ 903 or 904 thousandths, in order that, by the assay in the laboratory of the Mint, it should appear to have the standard of 900 thousandths. These 3 or 4 thousandths would be lost to him, since they would be disguised by the mode of assay, the definitive criterion of the quantity of silver, of which the Government keeps count from the coiner of the money.

From experiments subsequently made by M. D'Arcet, it appears that silver assays

Digitized by Google

always suffer a loss of the precious metal, which varies with the standard of the alloy. It is 1 thousandth for fine silver,

4·3 thousandths for silver of 900 thousandths,
4·9 „ „ 800 „
4·2 „ „ 500 „

and diminishes thereafter, progressively, till the alloy contains only 100 thousandths of silver, at which point the loss is only 0·4.

Assays requested by the Commission of the Paris Mint, from the assayers of the principal Royal Mints in Europe, to which the same alloys, synthetically compounded, were sent, afforded the results inscribed in the following Table: —

Names of the Assayers.	Cities where they reside.	Standards found for the Mathematical Alloys.		
		950 Mill.	900 Mill.	800 Mill.
F. de Castenhole, Mint Assayer	Vienna	946·20	898·40	795·10
A. R. Vervaëz, ditto	Madrid	944·40	893·70	789·20
D. M. Cabrera, Assayer in Spain	Ditto	944·40	893·70	788·60
Assayer	Amsterdam	947·00	895·00	795·00
Mr. Bingley, Assay Master	London	946·25	896·25	794·25
Mr. Johnson, Assayer	Ditto	933·33	883·50	783·33
Inspector of the Mint	Utrecht	945·00	896·50	799·00
Assayer of the Mint	Naples	945·00	891·00	787·00
Assayer of Trade	Ditto	945·00	891·00	787·00
Assayer of the Mint	Hamburg	946·$\frac{13}{12}$	897·$\frac{11}{12}$	798·$\frac{11}{12}$
Ditto	Altona	942·$\frac{1}{4}$	894·00	790

These results, as well as those in still greater numbers, obtained from the ablest Parisian assayers, upon identical alloys of silver and copper, prove that the mode of assay applied to them brings out the standard too low; and further, that the quantity of silver masked or disguised, is not uniform for these different eminent assay masters. An alloy, for example, at the standard of 900 thousandths is judged

at the Mint of Paris to have a standard of 895·6 mill.
„ Vienna „ 898·4 „
„ Madrid „ 893·7 „
„ Naples „ 891·0 „

The fact thus so clearly made out, of a loss in the standard of silver bullion and coin, merits the most serious attention; and it will appear astonishing, perhaps, that a thing recurring every day should have remained for so long a time in the dark. In reality, however, the fact is not new; as the very numerous and well-made experiments of Tillet from 1760 to 1763, which are related in the memoirs of the Academy of Sciences, show, in the silver assays, a loss still greater than that which was experienced in the laboratory of the Commission of the French Mint. But he thought that, as the error was common to the nations in general, it was not worth while or prudent to introduce any innovation.

A mode of assaying to give with certainty the standard of silver bullion, should be entirely independent of the variable circumstances of temperature, and the unknown proportions of copper, so difficult to regulate by the mere judgment of the senses. The process by the humid way, recommended to the Royal Mint in 1829, and exhibited as to its principles before the Right Honourable John Herries, then Master, in 1830, has all the precision and certainty we could wish. It is founded on the well-known property which silver has, when dissolved in nitric acid, to be precipitated in a chloride of silver quite insoluble by a solution of sea salt or by muriatic acid; but, instead of determining the weight of the chloride of silver, which would be somewhat uncertain and rather tedious on account of the difficulty of drying it, we take the quantity of the solution of sea salt which has been necessary for the precipitation of the silver. To put the process in execution, a liquor is prepared composed of water and sea salt in such proportions that 1000 measures of this liquor may precipitate completely 12 grains of silver, perfectly pure or of the standard 1000, previously dissolved in nitric acid. The liquor thus prepared gives, immediately, the true standard of any alloy whatever, of silver and copper, by the quantity of which it may be neccssary to precipitate 12 grains of this alloy. If, for example, 905 measures

Digitized by Google

have been required to precipitate the 12 grains of alloy, its standard would be 905 thousandths.

The process by the humid way is, so to speak, independent of the operator, the manipulations are so easy; and the term of the operation is very distinctly announced by the absence of any sensible nebulosities on the affusion of sea salt into the silver solution, while there remains in it one quarter of a thousandth of metal. The process is not tedious, and in experienced hands it may rival the cupel in rapidity: it has the advantage over the cupel as being more within the reach of ordinary operators, and of not requiring a long apprenticeship. It is particularly useful to such assayers as have only a few assays to make daily, as it will cost them very little time and expense.

By agitating briskly, during two minutes, the liquid rendered milky by the precipitation of the chloride of silver, it may be sufficiently clarified to enable us to appreciate, after a few moments of repose, the disturbance that can be produced in it by the addition of 1000th of a grain of silver. Filtration is more efficacious than agitation, especially when it is employed afterwards: it may be sometimes used; but agitation, which is much more prompt, is generally sufficient. The presence of lead and copper, or any other metal, except mercury, has no perceptible influence on the quantity of sea salt necessary to precipitate the silver; that is to say, the same quantitity of silver, pure or alloyed, requires for its precipitation a constant quantity of the solution of sea salt.

Supposing that we operate upon a gramme of pure silver, the solution of sea salt ought to be such that 100 centimetres cube may precipitate exactly the whole of the silver. The standard of an alloy is given by the number of thousandths of solution of sea salt necessary to precipitate the silver contained in a gramme of alloy.

When any mercury is accidentally present, which is, however, a rare occurrence, it is made obvious by the precipitated chloride remaining white when exposed to daylight; whereas, when there is no mercury present, it becomes speedily first grey and then purple. Silver so contaminated must be strongly ignited in fusion before being assayed, and its loss of weight noted. In this case, a cupel assay must be had recourse to.

Preparation of the Normal Solution of Sea Salt, when it is measured by Weight.—Supposing the sea salt pure as well as the water, we have only to take these two bodies in the proportion of 0·5427 k. of salt to 99·4573 k. of water, to have 100 k. of solution, of which 100 grammes will precipitate exactly one gramme of silver. But instead of pure salt, which is to be procured with difficulty, and which besides may be altered readily by absorbing the humidity of the air, a concentrated solution of the sea salt of commerce is to be preferred, of which a large quantity may be prepared at a time, to be kept in reserve for use, as it is wanted.—*Instruction de Gay-Lussac.*

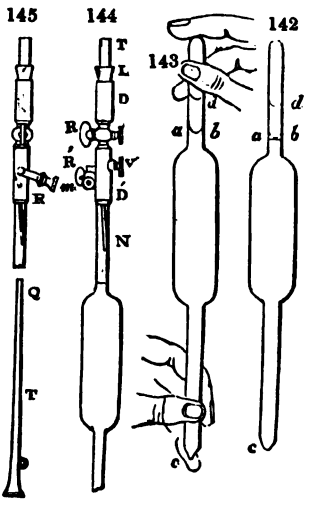
Preparation of the Normal Solution of Sea Salt, when measured by Volume.—The measure by weight has the advantage of being independent of temperature, of having the same degree of precision as the balance, and of not standing in need of correction. The measure by volume has not all these advantages; but, by giving it sufficient precision, it is more rapid, and is quite sufficient for the numerous daily assays of the Mint. This normal solution is so made, that a volume equal to that of 100 grammes of water, or 100 centimetres cube, at a determinate temperature, may precipitate exactly one gramme of silver. The solution may be kept at a constant temperature, and in this case the assay stands in no want of correction; or if its temperature be variable, the assay must be corrected according to its influence. These two circumstances make no change in the principle of the process, but they are sufficiently important to occasion some modifications in the apparatus. Experience has decided the preference in favour of applying a correction to a variable temperature.

We readily obtain a volume of 100 cubic centimetres by means of a *pipette, fig.* 142, so gauged, that when filled with water up to the mark *a, b,* and well dried at its point, it will run out, at a continuous efflux, 100 grammes of water at the temperature of 15°C. (59° F.) We say purposely at one efflux, because after the cessation of the jet, the pipette may still furnish two or three drops of liquid, which must not be counted or reckoned upon. The weight of the volume of the normal solution, taken in this manner with suitable precautions, will be uniform from one extreme to another, upon two centimetres and a half, at most, or to a quarter of a thousandth, and the difference from the mean will be obviously twice less, or one half. Let us indicate the most simple manner of taking a measure of the normal solution of sea salt.

After having immersed the beak, *c,* of the pipette in the solution, we apply suction, by the mouth, to the upper orifice, and thereby raise the liquid to *d,* above the circular line *a b.* We next apply neatly the forefinger of one hand to this orifice, remove the pipette from the liquid, and seize it as represented in *fig.* 143. The mark *a b* being placed at the level of the eye, we make the surface of the solution become exactly a

Digitized by Google

tangent to the plane *a b*. At the instant it becomes a tangent, we leave the beak, *c*, of *pipette* open, by taking away the finger that had been applied to it, and without changing anything else in the position of the hands, we empty it into the bottle which should receive the solution, taking care to remove it whenever the efflux has run out.

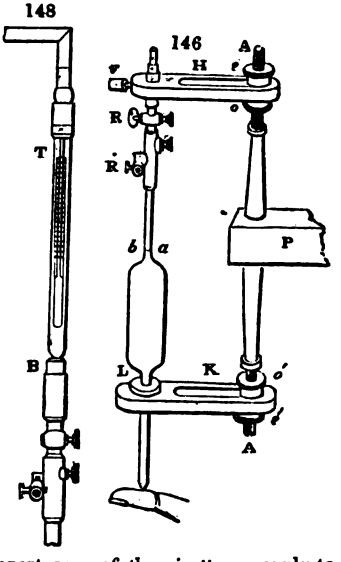


If, after filling the pipette by suction, anyone should find a difficulty in applying the forefinger fast enough to the upper orifice, without letting the liquid run down below the mark *a b*, he should remove the *pipette* from the solution with its top still closed with his tongue, then apply the middle finger of one of his hands to the lower orifice; after which he may withdraw his tongue, and apply the forefinger of the other hand to the orifice previously wiped. This method of obtaining a measure of normal solution of sea salt is very simple, and requires no complex apparatus; but we shall indicate another manipulation still easier, and much more exact.

In this new process the *pipette* is filled from the top like a bottle, instead of being filled by suction, and it is moreover fixed. *Fig.* 144 represents the apparatus. D and D′ are two sockets separated by a stopcock, R. The upper one, tapped interiorly, receives, by means of a cork stopper, L, the tube, T, which admits the solution of sea salt. The lower socket is cemented on to the *pipette*; it bears a small air-cock, R′, and a screw plug, V, which regulates a minute opening intended to let the air enter very slowly into the *pipette*. Below the stopcock, R′, a silver tube, N, of narrow diameter, soldered to the socket, leads the solution into the *pipette*, by allowing the air, which it displaces, to escape by the stopcock, R′. The screw plug, with the milled head, V, replaces the ordinary screw by which the key of the stopcock may be made to press, with more or less force, upon its conical seat.

Fig. 145 represents a side view of the apparatus just described. We here remark an air-cock R, and an opening *m*. At the extremity Q of the same figure, the conical pipe T enters with friction. It is by this pipe that the air is sucked into the *pipette*, when it is to be filled from its beak.

The *pipette* is supported by two horizontal arms H K (*fig.* 146) movable about a common axis, A A, and capable of being drawn out or shortened by the aid of two longitudinal slits. They are fixed steadily by two screw nuts, *e é*, and their distance may be varied by means of round bits of wood or cork interposed, or even by opposite screw nuts, *o ó*. The upper arm H is pierced with a hole, in which is fixed, by the pressure of a wooden screw *v*, the socket of the *pipette*. The corresponding hole of the lower arm is larger; and the beak of the *pipette* is supported in it by a cork stopper, L. The apparatus is fixed by its tail-piece P, by means of a screw to the corner of a wall, or any other prop.

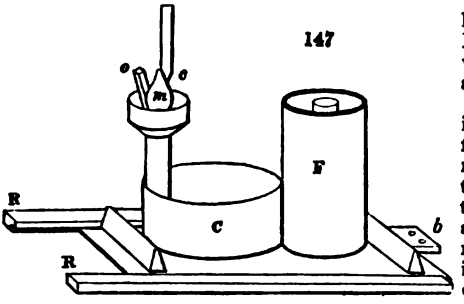


The manner of filling the *pipette* is very simple. We begin by applying the fore finger of the left hand to the lower aperture, *c*; we then open the two stopcocks R and R′. Whenever the liquor approaches the neck of the *pipette*, we must temper its influx, and when it has arrived at some millimetres above the mark *a b*, we close the two stopcocks, and remove our forefinger. We have now nothing more to do than to regulate the *pipette*; for which purpose the liquid must touch the line *a b*, and must simply adhere externally to the beak of the *pipette*.

This last circumstance is easily adjusted. After taking away the finger which closed the aperture *c* of the *pipette*, we apply to

Digitized by Google

this orifice a moist sponge *m*, *fig.* 147 to absorb the superfluous liquor as it drops out. This sponge is called the handkerchief (*mouchoir*), by M. Gay-Lussac. The *pipette* is said to be wiped when there is no liquor adhering to its point exteriorly.



For the convenience of operating, the handkerchief is fixed by friction in a tube of tin plate, terminated by a cup, open at bottom to let the droppings flow off into the cistern C, to which the tube is soldered. It may be easily removed for the purpose of washing it; and, if necessary, a little wedge of wood, *o*, can raise it towards the *pipette*.

To complete the adjustment of the *pipette*, the liquid must be made merely to descend to the mark *a*, *b*. With this view, and whilst the handkerchief is applied to the beak of the *pipette*, the air must be allowed to enter very slowly, by unscrewing the plug *v*, *fig.* 144; and at the moment of the contact the handkerchief must be removed, and the bottle F, destined to receive the solution, must be placed below the orifice of the *pipette*, *fig.* 147. As the motion must be made rapidly, and without hesitation, the bottle is placed in a cylinder of tin-plate, of a diameter of somewhat greater, and forming one body with the cistern and the handkerchief. The whole of this apparatus has for a basis a plate of tinned iron, movable between the wooden rulers R R, one of which bears a groove, under which the edge of the plate slips. Its traverses are fixed by two abutments, *b b*, placed so that when it is stopped by one of them, the beak of the *pipette*, corresponds to the centre of the neck of the bottle, or is a tangent to the handkerchief. This arrangement, very convenient for wiping the *pipette* and emptying it, gives the apparatus sufficient solidity, and allows of its being taken away, and replaced without deranging anything. It is obvious that it is of advantage, when once the entry of the air into the *pipette* has been regulated by the screw v, to leave it constantly open because the motion from the handkerchief to the bottle is performed with sufficient rapidity to prevent a drop of the solution from collecting and falling down.

Temperature of the Solution.—After having described the manner of measuring by volume the normal solution of the sea salt, we shall indicate the most convenient means of taking the temperature. The thermometer is placed in a tube of glass, T, *fig.* 148, which the solution traverses to arrive at the *pipette*. It is suspended in it by a piece of cork, grooved on the four sides to afford passage to the liquid. The scale is engraved upon the tube itself, and is repeated at the opposite side, to fix the eye by the coincidence of this double division at the level of the thermometric column. The tube is joined below to another narrower one, through which it is attached by means of a cork stopper B, in the socket of the stopcock of the *pipette*. At its upper part it is cemented into a brass socket, screw-tapped in the inside, which is connected in its turn by a cock, with the extremity, also tapped, of the tube above T, belonging to the reservoir of the normal solution. The corks employed here as connecting links between the parts of the apparatus, give them a certain flexibility, and allow of their being dismounted and remounted in a very short time; but it is indispensable to make them be traversed by a hollow tube of glass or metal, which will hinder them from being crushed by the pressure they are exposed to. If the precaution be taken to grease them with a little suet and to fill their pores, they will suffer no leakage.

Preservation of the Normal Solution of Sea Salt in metallic Vessels.—M. Gay-Lussac uses for this purpose a cylindrical vessel or drum of copper, of a capacity of about 110 litres, having its inside covered with a resin and wax cement.

Preparation of the Normal Solution of Sea Salt, measuring it by Volume. — If the drum contains 110 litres, we should only put 105 into it, in order that sufficient space may be left for agitating the liquor without throwing it out. According to the principle that 100 centimetres cube, or $\frac{1}{10}$th of a litre of the solution should contain enough of sea salt to precipitate a gramme of pure silver; and, admitting moreover, 13·516 for the equivalent of silver, and 7·335 for that of sea salt, we shall find the quantity of pure salt that should be dissolved in the 105 litres of water, and which corresponds to 105 × 10 = 1050 grammes of silver, to be by the following proportion:—

$$13{\cdot}516 : 7{\cdot}335 :: 1050 \text{ gramm.} : x = 569{\cdot}83 \text{ gr.}$$

And as the solution of the sea salt of commerce formerly mentioned contains approximatively 250 grammes per kilogramme, we must make 2279·3 grammes of this

Digitized by Google

solution to have 569·83 gram. of salt. The mixture being perfectly made, the tubes and the *pipette* must be several times washed by running the solution through them, and putting it into the drum. The standard of the solution must be determined after it has been well agitated, supposing the temperature to remain uniform.

To arrive more conveniently at this result, we begin by preparing two *decimes* solutions; one of silver, and another of sea salt.

The decime solution of silver is obtained by dissolving 1 gramme of silver in nitric acid, and diluting the solution with water till its volume becomes a litre.

The decime solution of sea salt may be obtained by dissolving 0·543 grammes of pure sea salt in water, so that the solution shall occupy a litre; but we shall prepare it even with the normal solution which we wish to test, by mixing a measure of it with 9 measures of water; it being understood that this solution is not rigorously equivalent to that of silver, and that it will become so only when the normal solution employed for its preparation shall be finally of the true standard. Lastly, we prepare beforehand several stoppered phials, in each of which we dissolve 1 gramme of silver in 8 or 10 grammes of nitric acid. For brevity's sake, we shall call these "tests."

Now to investigate the standard of the normal solution, we must transfer a *pipette* of it into one of these test phials; and we must agitate the liquors briskly to clarify them. After some instants of repose, we pour in 2 thousandths of the *decime* solution of sea salt, which we suppose will produce a precipitate. The normal liquor is consequently too feeble; and we should expect this, since the salt employed was not perfectly pure. We agitate and add 2 fresh thousandths, which will also produce a precipitate. We continue thus, by successive additions of 2 thousandths, till the last produces no precipitation. Suppose that we have added 16 thousandths: the last two should not be reckoned, as they produced no precipitate; the preceding two were necessary, but only in part; that is to say, the useful thousandths added are above 12 and below 14, or otherwise they are on an average equal to 13.

Thus, in the condition of the normal solution, we require 1013 parts of it to precipitate one gramme of silver, while we should require only 1000. We shall find the quantity of concentrated solution of sea salt that we should add, by noting that the quantity of solution of sea salt, at first employed, viz. 2279·3 grammes, produced a standard of only 987 thousandths = 1000 — 13; and by using the following proportion:

$$987 : 2279{\cdot}3 :: 13 : x = 30{\cdot}02 \text{ grammes.}$$

This quantity of the strong solution of salt, mixed with the normal solution in the drum, will correct its standard, and we shall see now by how much.

After having washed the tubes and the *pipette* with the new solution, we must repeat the experiment upon a fresh gramme of silver. We shall find, for example, in proceeding only by a thousandth at a time, that the first causes a precipitate, but not the second. The standard of the solution is still too weak, and is comprised between 1000 and 1001; that is to say, it may be equal to $1000\frac{1}{2}$, but we must make a closer approximation.

We pour into the test bottle 2 thousandths of the *decime* solution of silver, which will destroy 2 thousandths of sea salt, and the operation will have retrograded by 2 thousandths; that is to say, it will be brought back to the point at which it was first of all. If, after having cleared up the liquor, we add half a thousandth of the decime solution, there will necessarily be a precipitate, as we knew beforehand, but a second will cause no turbidity. The standard of the normal liquor will be consequently comprehended between 1000 and $1000\frac{1}{2}$, or equal to $1000\frac{1}{4}$.

We should rest content with this standard, but if we wish to correct it, we may remark that the two quantities of solution of salt added, viz. 2279·3 gr. + 30·02 gr. = 2309·32 gr., have produced only 999·75 thousandths, and that we must add a new quantity of it corresponding to $\frac{1}{4}$ of a thousandth. We make, therefore, the proportion

$$999{\cdot}75 : 2309{\cdot}32 :: 0{\cdot}25 : x.$$

But since the first term differs very little from 1000, we may content ourselves to have x by taking the $\frac{0{\cdot}25}{1000}$ of 2309·32, and we shall find 0·577 gr. for the quantity of solution of sea salt to be added to the normal solution.

It is not convenient to take exactly so small a quantity of solution of sea salt by the balance, but we shall succeed easily by the following process. We weigh 50 grammes of this solution, and we dilute it with water, so that it occupies exactly half a litre, or 500 centimetres cube. A *pipette* of this solution, one centimetre cube in volume, will give a decigramme of the primitive solution, and as such a small *pipette* is divided into twenty drops, each drop, for example, will present 5 milligrammes of

Digitized by Google

the solution. We should arrive at quantities smaller still by diluting the solution with a proper quantity of water; but greater precision would be entirely needless.

The testing of the normal liquor just described is, in reality, less tedious than might be supposed. It deserves also to be remarked, that liquor has been prepared for more than 1000 assays; and that, in preparing a fresh quantity, we shall obtain directly its true standard, or nearly so, if we bear in mind the quantities of water and solution of salt which have been employed.

Correction of the Standard of the Normal Solution of Sea Salt, when the Temperature changes. — We have supposed, in determining the standard of the normal solution of sea salt, that the temperature remained uniform. The assays made in such circumstances have no need of correction; but if the temperature should change, the same measure of the solution will not contain the same quantity of sea salt. Supposing that we have tested the solution of the salt at the temperature of 15° C.; if, at the time of making the experiment, the temperature is 18° C., for example, the solution will be too weak on account of its expansion, and the *pipette* will contain less of it by weight; if, on the contrary, the temperature has fallen to 12°, the solution will be thereby concentrated, and will prove too strong. It is therefore proper to determine the correction necessary to be made for any variation of temperature.

To ascertain this point, the temperature of the solution of sea salt was made successively, to be 0, 5°, 10°, 15°, 20°, 25°, and 30° C.; and three *pipettes* of the solution were weighed exactly at each of these temperatures. The third of these weighings gave the mean weight of a *pipette*. The corresponding weights of a *pipette* of the solution were afterwards graphically interpolated from degree to degree. These weights form the second column of the following Table. They enable us to correct any temperature between 0° and 30° C. (32° and 86° F.) when the solution of sea salt has been prepared in the same limits.

Table of Correction for the Variations in the Temperature of the Normal Solution of the Sea Salt.

Temperature.	Weight.	5°	10°	15°	20°	25°	30°
Degrees.	Gram.	Mill.	Mill.	Mill.	Mill.	Mill.	Mill.

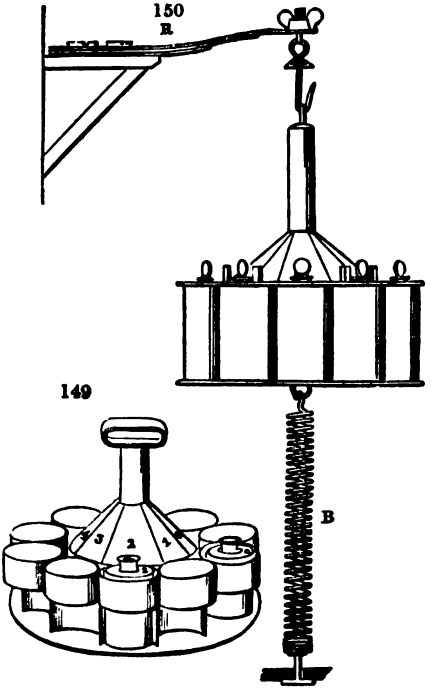
30	99,836	−2·8	−2·8	−2·6	−2·0	−1·1	0·0

Let us suppose, for example, that the solution has been made standard at 15°, and that at the time of using it, the temperature has become 18°. We see by the second column of the Table, that the weight of a measure of the solution is 100·099 gr. at 15°, and 100·065 at 18°; the difference, 0·034 gr., is the quantity of solution less which

Digitized by Google

has been really taken; and of course we must add it to the normal measure, in order to make it equal to one thousand *millièmes*. If the temperature of the solution had fallen to 10° the difference of the weight of a measure from 10° to 15° would be 0·019 gr., which we must on the contrary deduct from the measure, since it had been taken too large. These differences of weight of a measure of solution at 15°, from that of a measure at any other temperature, form the column 15° of the table, where they are expressed in thousandths; they are inscribed on the same horizontal lines as the temperatures to which each of them relates with the sign + *plus*, when they must be added, and with the sign — *minus*, when they must be subtracted. The columns 5°, 10°, 20°, 25°, 35°, have been calculated in the same manner for the cases in which the normal solution may have been graduated to each of these temperatures. Thus, to calculate the column 10°, the number 100·118 has been taken in the column of weights for a term of departure, and its difference from all the numbers of the same column has been sought.

Several expedients have been employed to facilitate and abridge the manipulations. In the first place, the phials for testing or assaying the specimens of silver should all be of the same height and of the same diameter. They should be numbered at their top, as well as on their stoppers, in the order 1, 2, 3, &c. They may be ranged successively in tens; the stoppers of the same series being placed on a support in their proper order. Each two phials should, in their turn, be placed in a japanned tin case (*fig.* 149) with ten compartments, duly numbered. These compartments are cut out anteriorly to about half their height, to allow the bottoms of the bottles to be seen. When each phial has received its portion of alloy, through a wide-beaked funnel, there must be poured into it about 10 grammes of nitric acid, of specific gravity 1·28, with a *pipette*, containing that quantity; it is then exposed to the heat of a water bath, in order to facilitate the solution of the alloy. The water bath is an oblong vessel made of tin plate, intended to receive the phials. It has a movable double bottom, pierced with small holes, for the purpose of preventing the phials being broken, as it insulates them from the bottom, to which the heat is applied. The solution is rapid; and, since it emits nitrous vapours in abundance, it ought to be carried on under a chimney.



The Agitator.—*Fig.* 150 gives a sufficiently exact idea of it, and may dispense with a lengthened description. It has ten cylindrical compartments, numbered from 1 to 10. The phials, after the solution of the alloy, are arranged in it in the order of their numbers. The agitator is then placed within reach of the *pipette* intended to measure out the normal solution of sea salt, and a *pipette* full of this solution is put into each phial. Each is then closed with its glass stopper, previously dipped in pure water. They are fixed in the cells of the agitator by springs. The agitator is then suspended to a spring R, and, seizing it with both hands, the operator gives an alternating rapid movement, which agitates the solution, and makes it, in less than a minute, as limpid as water. This movement is sometimes promoted by a spiral spring, B, fixed to the agitator and the ground; but this is seldom made use of, because it is convenient to be able to transport the agitator from one place to another. When the agitation is finished, the catches are released, and the phials are placed in order upon a table furnished with round cells destined to receive them, and to screen them.

When we place the phials upon this table, we must give them a brisk circular motion to collect the chloride of silver scattered round their sides; we must lift out their

Digitized by Google

stoppers, and suspend them in wire rings, or pincers. We next pour a thousandth of the decime solution into each phial; and before this operation is terminated, there is formed in the first phials, when there *should be* a precipitate, a nebulous stratum, very well marked, of about a centimetre in thickness.

At the back of the table there is a black board divided into compartments, numbered from 1 to 10, upon each of which we mark, with chalk, the thousandths of the decime liquor put into the corresponding phial. The thousandths of sea salt, which indicate an augmentation of standard, are preceded by the sign +, and the thousandths of nitrate of silver by the sign —.

When the assays are finished, the liquor of each phial is to be poured into a large vessel in which a slight excess of sea salt is kept; and when it is full, the supernatant clear liquid must be run off with a siphon.

The chloride of silver may be reduced without any perceptible loss. After having washed it well, we immerse pieces of zinc in it, and add sulphuric acid in sufficient quantity to keep up a feeble disengagement of hydrogen gas. The mass must not be touched. In a few days the silver is completely reduced. This is easily recognised by the colour and nature of the product; or by treating a small quantity of it with water of ammonia, we shall see whether there be any chloride unreduced; for it will be dissolved by the ammonia, and will again appear upon saturating the ammonia with an acid. The chlorine remains associated with the zinc in a state of solution. The first washings of the reduced silver must be made with an acidulous water, to dissolve the oxides which may have been formed, and the other washings with common water. After decanting the water of the last washing, we dry the mass, and add to it a little powdered borax. It must now be fused. The silver being in a bulky powder is to be put in successive portions into a crucible as it sinks down. The heat should be at first moderate; but towards the end of the operation, it must be pretty strong, to bring into complete fusion the silver and the scoriæ, and to effect their complete separation. In case it should be supposed that the whole of the silver had not been reduced by the zinc, a little carbonate of potash should be added to the borax. The silver may also be reduced by exposing the chloride to a strong heat, in contact with chalk and charcoal.

The following remarks by M. Gay-Lussac, the author of the above method, upon the effect of a little mercury in the humid assay, are important: —

It is well known that chloride of silver blackens the more readily when it is exposed to an intense light, and that even in the diffused light of a room it becomes soon sensibly coloured. If it contains four to five thousandths of mercury, it does not blacken; it remains of a dead white: with three thousandths of mercury, there is no marked discolouring in diffused light; with two thousandths it is slight; with one it is much more marked, but still it is much less intense than with pure chloride. With half a thousandth of mercury the difference of colour is not remarkable, and is perceived only in a very moderate light.

But when the quantity of mercury is so small that it cannot be detected by the difference of colour in the chloride of silver, it may be rendered quite evident by a very simple process of concentration. Dissolve one gramme of the silver supposed to contain $\frac{1}{4}$ of a thousandth of mercury, and let only $\frac{1}{4}$ of it be precipitated, by adding $\frac{1}{4}$ of the common salt necessary to precipitate it entirely. In thus operating, the $\frac{1}{4}$ thousandth of mercury is concentrated in a quantity of chloride of silver four times smaller: it is as if the silver having been entirely precipitated, four times as much mercury, equal to two thousandths, had been precipitated with it.

On taking two grammes of silver, and precipitating only $\frac{1}{4}$ by common salt, the precipitate would be, with respect to the chloride of silver, as if it amounted to four thousandths. By this process, which occupies only five minutes because exact weighing is not necessary, $\frac{1}{10}$th of a thousandth of mercury may be detected in silver.

It is not useless to observe that, in making those experiments, the most exact manner of introducing small quantities of mercury into a solution of silver, is to weigh a minute globule of mercury, and to dissolve it in nitric acid, diluting the solution so that it may contain as many cubic centimetres as the globule weighs of centigrammes. Each cubic centimetre, taken by means of a *pipette*, will contain one milligramme of mercury.

If the ingot of silver to be assayed be found to contain a greater quantity of mercury —one thousandth, for example—the humid process ought, in this case, either to be given up or to be compared with cupellation.

When the silver contains mercury, the solution from which the mixed chlorides are precipitated does not really become clear.

Silver containing mercury, put into a small crucible, and mixed with lamp black, to prevent the volatilisation of the silver, was heated for three quarters of an hour in a muffle, but the silver increased sensibly in weight. This process for separating the

Digitized by Google

mercury, therefore, failed. It is to be observed, that mercury is the only metal which has thus the power of disturbing analysis by the humid way.

The error caused by the presence of mercury may be avoided by the addition of a small quantity of acetate of soda to the solution of the silver in nitric acid, previous to addition of the chloride of sodium, as this salt prevents the precipitation of the mercury.—*Levol, Gay-Lussac.*

The process employed in assaying gold bullion, by the present assayers to the Mint and Bank of England, is similar to that practised at the Paris Mint. The quantity operated on is half a gramme. This quantity, having been accurately weighed, is wrapped in paper with a portion of pure silver, about equal to three times that of the gold the alloy is supposed to contain, and submitted to cupellation with lead in the manner above described. The button is then hammered into a flattened dish, about the size of a sixpence, and afterwards annealed and passed through laminating rolls until it is reduced to a riband from 2½ to 3 inches in length; after which it is again annealed, and coiled into a spiral by rolling between the finger and thumb. The *cornet* is next placed in a small flask containing about an ounce of pure nitric acid of 22 B. (= 1·180 specific gravity), and boiled for 10 minutes. The acid is carefully poured off, and the cornet again boiled with nitric acid of 32 B. (1·280 specific gravity) for 20 minutes; and this second boiling with the stronger acid is repeated and continued about 10 minutes. In the second and third boilings a small piece of charcoal should be introduced into the flask, as recommended by Gay-Lussac, in order to prevent the ebullition taking place irregularly and with sudden bursts, which would be liable to break the cornet, and eject a portion of the liquid from the flask. The cornet is then washed and annealed as above. The return is made to the Mint in decimals or thousandths, and the assayer's weights are so subdivided as to give him the value in thousandths of the original ½ gramme taken.

To the Bank the return is made to the ¼th of a carat grain better or worse than standard. The late Master of the Mint caused Tables to be prepared for the conversion of the reports of assays expressed in carats into decimals, and conversely, which are in general use for this purpose. In order to ascertain the amount of error due to the surcharge, a number of *proofs* are passed through the process simultaneously with the alloys. These proofs consist of weighed portions of absolutely pure gold, to which are added a proportion of copper equal to that estimated to exist in the alloy to be assayed. The excess of weight in these proofs gives the amount to be deducted. It generally varies from 0·2 to 0·5 parts in 1000.

The last traces of silver may be removed from the cornet by treating it before the final annealing with fusing bisulphate of potash in a porcelain crucible. When sufficiently cool, the whole is heated with hot water containing a little sulphuric acid, and the cornet dried and ignited. By this means gold may be obtained of almost absolute purity, or $\frac{1000}{1000}$, as it is termed.

The following examples will show the difference in the results, and the degree of accuracy attainable, by the various methods described.

Ten grains of pure gold, alloyed with three times its weight of silver, cupelled and boiled with acid at 22° B., and 32° B., once weighed 10·016.

Ten grains of a half-sovereign, with silver, &c., and acid at 22°, and twice at 32° B.,

gave 915·4
again, 915·6

With acid, as before, and bisulphate of potash, 915·2
again, 915·2

Pure gold alloyed with copper, to bring it to standard, cupelled with silver and lead, and treated with acids and bisulphate, gave in one case precisely the same as was taken originally, or $\frac{1000}{1000}$, and in another 999·98.

In accurate assaying of gold bullion, it is of course absolutely necessary that the acids should be pure, and that the silver used should be most carefully freed from the traces of gold which it usually contains.

Instead of charcoal or coke, which are generally used for cupellation, much advantage has been found in employing the best anthracite: reduced to the proper size, it contains very little ash, is free from slag or clinker, and allows the heat to be maintained at one steady temperature for many hours, which is a matter of great importance to the assayer.*

ASSAYING OF GOLD.—In estimating or expressing the fineness of gold, the whole mass spoken of is supposed to weigh 24 carats of 12 grains each, either real, or merely

* The most useful works on this subject are,— Chaudet, "L'Art de l'Essayeur;" the work of Gay-Lussac mentioned in the text; "Manuel complet de l' Essayeur," par Vauquelin and D'Arcet, edited by Vergnaud, Paris, 1836 (a most useful little work); Bodemann, "Anleitung zur Berg- und Huttenmannischen Probierkunst," Clausthal, 1815; (and perhaps the best of them all) the "Scheikundig Handbock voor Essaijeurs Goud und Zilversmeden" by Stratingh, Groningen, 1821.

Digitized by Google

proportional, like the assayer's weights; and the pure gold is called fine. Thus, if gold be said to be 23 carats fine, it is to be understood that, in a mass weighing 24 carats, the quantity of pure gold amounts to 23 carats.

In such small work as cannot be assayed by scraping off a portion and cupelling it, the assayer endeavours to ascertain its fineness or quality by the touch. This is a method of comparing the colour and other properties of a minute portion of the metal with those of small bars, the composition of which is known. These bars are called touch-needles, and are rubbed upon a smooth piece of black basalt or pottery, which, for this reason, is called the touchstone. Black flint slate will serve the same purpose. Sets of gold needles may consist of pure gold; of gold, 23½ carats with ½ carat of silver; 23 carats of gold with one carat of silver; 22½ carats of gold with 1½ carat of silver; and so on, till the silver amounts to four carats; after which the additions may proceed by whole carats. Other needles may be made in the same manner, with copper instead of silver; and other sets may have the addition, consisting either of equal parts of silver and copper, or of such proportions as the occasions of business require. The examination by the touch may be advantageously employed previous to quartation, to indicate the quantity of silver necessary to be added.

In foreign countries, where trinkets and small work are required to be submitted to the assay of the touch, a variety of needles is necessary, but they are not much used in England. They afford, however, a degree of information which is more considerable than might at first be expected. The attentive assayer compares not only the colour of the stroke made upon the touchstone by the metal under examination with that produced by his needle, but will likewise attend to the sensation of roughness, dryness, smoothness, or greasiness, which the texture of the rubbed metal excites when abraded by the stone. When two strokes perfectly alike in colour are made upon the stone, he may then wet them with aquafortis, which will affect them very differently if they be not of similar compositions; or the stone itself may be made red-hot by the fire, or by the blowpipe, if thin black pottery be used; in which case the phenomena of oxidation will differ according to the nature and quantity of the alloy. Six principal circumstances appear to affect the operation of parting; namely, the quantity of acid used in parting, or in the first boiling; the concentration of this acid; the time employed in its application; the quantity of acid made use of in the *reprise*, or second operation; its concentration; and the time during which it is applied. From experiment, it has been shown that each of these unfavourable circumstances might easily occasion a loss of from the half of a thirty-second part of a carat, to two thirty-second parts. The assayers explain their technical language by observing that, in the whole mass consisting of twenty-four carats, this thirty-second part denotes 1-768th part of the mass. It may easily be conceived, therefore, that if the whole six circumstances were to exist, and be each productive of errors falling the same way, the loss would be very considerable.

It is therefore indispensably necessary that one uniform process should be followed in the assays of gold; and it is a matter of astonishment that such an accurate process should not have been prescribed by Government for assayers, in an operation of such great commercial importance, instead of everyone being left to follow his own judgment. The process recommended in the old French official report is as follows: Twelve grains of the gold intended to be assayed must be mixed with thirty grains of fine silver, and cupelled with 108 grains of lead. The cupellation must be carefully attended to, and all the imperfect buttons rejected. When the cupellation is ended, the button must be reduced, by lamination, into a plate of 1½ inches, or rather more, in length, and four or five lines in breadth. This must be rolled up upon a quill, and placed in a matrass capable of holding about three ounces of liquid, when filled up to its narrow part. Two ounces and a half of very pure aquafortis, of the strength of 20 degrees of Baumé's areometer, must then be poured upon it; and the matrass being placed upon hot ashes, or sand, the acid must be kept gently boiling for a quarter of an hour: the acid must then be cautiously decanted, and an additional quantity of 1½ ounces must be poured upon the metal, and slightly boiled for twelve minutes. This being likewise carefully decanted, the small spiral pieces of metal must be washed with filtered river water, or distilled water, by filling the matrass with this fluid. The vessel is then to be reversed, by applying the extremity of its neck against the bottom of a crucible of fine earth, the internal surface of which is very smooth. The annealing must now be made, after having separated the portion of water which had fallen into the crucible; and lastly, the annealed gold must be weighed. For the certainty of this operation, two assays must be made in the same manner, together with a third assay upon gold of twenty-four carats, or upon gold the fineness of which is perfectly and generally known.

No conclusion must be drawn from this assay, unless the latter gold should prove to

Digitized by Google

be of the fineness of twenty-four carats exactly, or of its known degree of fineness; for, if there be either loss or surplus, it may be inferred that the other two assays, having undergone the same operation, must be subject to the same error. The operation being made according to this process by several assayers, all the assayers must have obtained an uniform result without communication with each other.

The phenomena of the cupellation of gold are the same as of silver, only the operation is less delicate, for no gold is lost by evaporation or penetration into the bone-ash, and therefore it bears safely the highest heat of the assay furnace. The button of gold never vegetates or spits, and need not therefore be drawn out to the front of the muffle, but may be left at the further end till the assay is complete. Copper is retained more strongly by gold than it is by silver; so that with it 16 parts of lead are requisite to sweat out 1 of copper; or, in general, twice as much lead must be taken for the copper alloys of gold as for those of silver. When the copper is alloyed with very small quantities of gold, cupellation would afford very uncertain results; we must then have recourse to liquid analysis.

M. Vauquelin recommends to boil 60 parts of nitric acid at 22° Baumé, on the spiral slip, or cornet of gold and silver alloy, for twenty-five minutes, and replace the liquid afterwards by acid of 32°, which must be boiled on it for eight minutes. This process is free from uncertainty, when the assay is performed upon an alloy containing a considerable quantity of copper. But this is not the case in assaying finer gold; for then a little silver always remains in the gold. The surcharge which occurs here is 2 or 3 thousandths; this is too much, and it is an intolerable error when it becomes greater, which often happens. This evil may be completely avoided by employing the following process of M. Chaudet. He takes 0·500 of the fine gold to be assayed; cupels it with 1·500 of silver and 1·000 of lead; forms, with the button from the cupel, a riband or strip three inches long, which he rolls into a cornet. He puts this into a matrass with acid at 22° B., which he boils for 3 or 4 minutes. He replaces this by acid of 32° B., and boils for ten minutes; then decants off, and boils again with acid of 32°, which must be finally boiled for 8 or 10 minutes.

Gold thus treated is very pure. He washes the cornet, and puts it entire into a small crucible permeable to water; heats the crucible to dull redness under the muffle, when the gold assumes the metallic lustre and the cornet becomes solid. It is now taken out of the crucible and weighed.

When the alloy contains platinum, the assay presents greater difficulties. In general, to separate with accuracy the platinum from the gold, we must avail ourselves of a peculiar property of platinum; when alloyed with silver, it becomes soluble in nitric acid. Therefore, by a proper quartation of the alloy by cupellation, and boiling the button with nitric acid, we may get a residuum of pure gold. If we were to treat the button with sulphuric acid, however, we should dissolve nothing but the silver. The copper is easily removed by cupellation. Hence supposing that we have a quarternary compound of copper, silver, platinum, and gold, we first cupel it, and weigh the button obtained; the loss denotes the copper. This button, treated by sulphuric acid, will suffer a loss of weight equal to the amount of silver present. The residuum, by quartation with silver and boiling with nitric acid, will part with its platinum, and the gold will remain pure. For more detailed explanations, see PLATINUM. For the analysis of ores, see the individual metals.—T. H. H.

ASTERIA (*Starstone*). The name first used by Pliny, to denote those varieties of sapphire which display diverging rays of light.

151

ASTRAGAL. An ornamental moulding, generally used to conceal a junction in either wood or stone.

ASTRAGAL PLANES. Planes fitted with cutters for forming astragal mouldings. They are commonly known as moulding planes.

ASTRAGAL TOOL, for turning. By using a tool shaped as in *fig.* 151, the process of forming a moulding or ring is greatly facilitated, as one member of the moulding is completed at one sweep, and we are enabled to repeat it any number of times with exact uniformity.

ASTRALITE. A glass resembling AVENTURINE (which see), but containing crystals of a compound of copper, which by reflected light exhibit a dichroitic iridescence of dark red and greenish-blue. It is said to be made with 80 parts of flint, 120 parts of oxide of lead, 72 parts of carbonate of soda, and 18 parts of anhydrous borax. To this is added 24 parts of scale oxide of copper, and 1 part of scale oxide of iron. These are melted in a Hessian crucible, at the heat of an ordinary air furnace, and left to cool slowly without being moved.

ATHERINA. See SARDINE.

ATMOMETER (*ἀτμὸς, vapour; μέτρον, a measure*). An instrument to measure

Digitized by Google

the quantity of water evaporated in a given time under ordinary atmospheric conditions.

ATACAMITE. A native oxychloride of copper, originally found in the desert of Atacama in Peru. It forms small rhombic crystals, varying in colour from leek to emerald green.

ATOM. (*ἀ, not; τεμνω, I cut.*) An indivisible particle.

With few exceptions, the views promulgated by Dr. Dalton are received by chemists. They may be thus expressed: All elementary bodies are formed of individual atoms, the different species of which unite, generally by twos, in a small number of groups, constituting compound atoms of the first order, always mechanically indivisible, but chemically divisible, and, in their turn, constituting all the other orders of composition by a series of analogous combinations.

We are not enabled by direct experiment to determine the condition of any ultimate atom of matter; but the results furnished by chemical science clearly point to the existence of elementary units, from which all the infinite varieties of matter are formed. Sir Isaac Newton thus expresses himself:—"All things considered, it seems probable that God, in the beginning, formed matter in solid, massy, hard, impenetrable, movable particles, of such sizes, figures, and with such other properties, and in such proportions to space, as most conduced to the end for which He formed them; and that these primitive particles, being solids, are incomparably harder than any porous bodies compounded of them; even so hard as never to wear or break to pieces; no ordinary power being able to divide what God Himself made one in the first creation. While the particles continue entire, they may compose bodies of one and the same nature and texture in all ages; but should they wear away, or break in pieces, the nature of things depending on them would be changed. Water and earth composed of old worn particles would not be of the same nature and texture now with water and earth composed of entire particles at the beginning. And therefore, that nature may be lasting, the changes of corporeal things are to be placed only in various separations, and new associations, and motions of these permanent particles; compound bodies being apt to break, not in the midst of solid particles, but where those particles are laid together and touch in a few points."—*Horsley's Newton.*

With the metaphysical theories, which would lead us to regard all matter as mere accumulations of force, it would not be proper at present to deal.

Experimental philosophy has proved to us that the conditions of matter are determined by certain *polar-attractive* forces; and that these are opposed or balanced by *heat, electricity,* and the force which regulates chemical combination. Consequently every ultimate atom of matter must be regarded as the centre of such a set of physical forces surrounding it as an atmosphere.

ATOMIC THEORY. The question as to whether matter be or be not infinitely divisible, has been debated from the earliest times, and is probably as far from a settlement as ever; we can, however, scarcely conceive of the existence of matter at all, if there be no limit to its divisibility. It is easy to demonstrate that a mathematical line is infinitely divisible, but a mathematical line is only an ideal thing; having only one dimension, it can have no physical existence. We have, therefore, no hesitation in admitting the existence of atoms of matter—of particles infinitely small, it is true, as regards our perceptions, far exceeding in minuteness the finest subdivision to which we can submit a body, but yet incapable of further subdivision. To such insectible molecules the term *atom* has been applied.

If we take any substance chemically complex, we may suppose the existence of atoms in this body, held together by the force of cohesion, which are themselves heterogeneous, being made up, in fact, of atoms of the elementary chemical constituents.

Dr. Dalton suggested the happy idea, which has been most fruitful in its results, of accounting for the constancy of chemical combinations by assuming that they were composed of one or more atoms of the several elements, the weight of which atoms is represented by the combining proportions; that carbonic oxide, for instance, contains single atoms of carbon and oxygen, whilst carbonic acid is composed of one atom of carbon and two of oxygen.

It must always be remembered that the combining proportions are purely the results of experiment, and, therefore, incontestable, whatever may be the fate of this theory, which, however, has now stood its ground for many years, and done excellent service to science.

This theory offers a most satisfactory explanation of the different laws of chemical combination.

The fact of bodies uniting only in certain proportions, or multiples of those proportions, is a necessary consequence of the assumption that the weight of the elementary atoms is represented by the combining proportions; for, if they united in

Digitized by Google

any other ratio, it would involve the splitiing up of these atoms, which are assumed to be indivisible.

And, of course, the combining proportion of a compound must be the sum of the combining proportions of the constituents, since it contains within itself one or more atoms of the several constituents.

The term atom is, therefore, very often used instead of combining proportion or equivalent, a body being said to contain so many atoms of its elements.

All that is assumed in this theory is, that the atoms are of constant value *by weight*; the same atoms may be arranged in a different way, and hence, although any particular compound contains always the same elements in the atomic ratios, yet the same atoms may, by difference in arrangement, give rise to bodies agreeing in composition by weight, but differing essentially in properties. See ISOMERISM.

M. Dumas has suggested the subdivision of the combining numbers of certain elements, but this idea is quite subversive of the atomic theory, as it is at present understood.

The atomic theory is further confirmed by the observation, that if the specific heat of the elements be compared, it is found that in a large number of cases the specific heat of quantities of the bodies represented by the atomic weights coincides with each other in a remarkable manner.

The Atomic Theory of Dalton is thus set forth by the author:—

"When any body exists in the elastic state, its ultimate particles are separated from each other to a much greater distance than in any other state; each particle occupies the centre of a comparatively large sphere, and supports its dignity by keeping all the rest—which, by their gravity, or otherwise, are disposed to encroach on it—at a respectful distance. When we attempt to conceive the number of particles in an atmosphere, it is somewhat like attempting to conceive the number of stars in the universe—we are confounded with the thought. But if we limit the subject, by taking a given volume of any gas, we seem persuaded that, be the divisions ever so minute, the number of particles must be finite; just as in a given space of the universe, the number of stars and planets cannot be infinite.

"Chemical analysis and synthesis go no further than to the separation of particles one from another, and to their reunion. No new creation or destruction of matter is within the reach of chemical agency. We might as well attempt to introduce a new planet into the solar system, or to annihilate one already in existence, as to create or destroy a particle of hydrogen. All the changes we can produce consist in separating particles that are in a state of cohesion or combination, and joining those that were previously at a distance.

"In all chemical investigations it has justly been considered an important object to ascertain the relative *weights* of the simples which constitute a compound. But, unfortunately, the inquiry has terminated there; whereas, from the relative weights in the mass, the relative weights of the ultimate particles or atoms of the bodies might have been inferred, from which their number and weights in various other compounds would appear, in order to assist and to guide future investigations, and to correct their results. Now it is one great object of this work ('A new System of Chemical Philosophy') to show the importance and advantage of ascertaining *the relative weights of the ultimate particles, both of simple and compound bodies, the number of simple elementary particles which constitute one compound particle, and the number of less compound particles which enter into the formation of each more compound particle.*

"If there are two bodies, A and B, which are disposed to combine, the following is the order in which combination may take place, beginning with the most simple, namely:

1 atom of A + 1 atom of B = 1 atom of C, binary.
1 atom of A + 2 atoms of B = 1 atom of D, ternary.
2 atoms of A + 1 atom of B = 1 atom of E, ternary.
1 atom of A + 3 atoms of B = 1 atom of F quaternary.
3 atoms of A + 1 atom of B = 1 atom of G quaternary.
&c. &c.

"The following general rules may be adopted as guides in all our investigations respecting chemical synthesis:—

"1. When only one combination of two bodies can be obtained, it must be presumed to be a binary one, unless some cause appears to the contrary.

"2. When two combinations are observed, they must be presumed to be binary or ternary.

"3. When three combinations are obtained, we may expect one to be binary and the other two ternary.

"4. When four combinations are observed, we should expect one binary, two ternary, and one quaternary.

Digitized by Google

"5. A binary compound should always be specifically heavier than the mere mixture of its two ingredients.

"6. A ternary compound should be specifically heavier than the mixture of a binary and a simple, which would, if combined, constitute it, &c.

"7. The above rules and observations equally apply when two bodies, such as C and D, D and E, &c., are combined."*

For a full examination of this subject, consult "An Introduction to the Atomic Theory," by Charles Daubeny, M.D.; and "Memoirs of John Dalton and History of the Atomic Theory," by Robert Angus Smith, Ph. D.

The following exemplification of the use of this theory is given by the former of those authors:—

"Let us suppose that we have obtained from a given quantity of the substance under examination 100 grains of a salt consisting of sulphuric acid, with unknown proportions of soda and potass, but with no other ingredient. Let us set down the quantity of acid at 50 grains, from which it will follow that the weight of the two bases will together make up the remaining moiety. Now had the whole of this latter consisted of soda, the quantity of acid should have been only forty grains, because the atomic weight of sulphuric acid is 40, whilst that of soda is 32, and

as 40 : 32 :: 50 : 40

On the contrary, if the whole had been potass, then as the atomic weight of this latter is 48, the amount required to neutralise the acid would have been 60 grains; for

as 40 : 48 :: 50 : 60.

But, if we suppose half the acid to be combined with the one alkali, and half with the other, then, and only then, will the weight of the salt correspond exactly with that obtained in the experiments before us; for

as 40 : 48 :: 25 : 30; and
as 40 : 32 :: 25 : 20

50 + 50 = 100

It is easy to apply this to the case of salts containing bromine together with chlorine, assuming that we are sufficiently acquainted with the respective atomic weights of both these principles.

"The bromide and chloride of sodium are alike precipitated by nitrate of silver in the form of an insoluble bromide and chloride of that metal: now the atomic weight

Of silver is stated to be	- - -	110
„ chlorine	- - - - -	36
„ bromine	- - - - -	78·4

Suppose, therefore, we have found the precipitate to weigh 151 grains; and that, of these, 100 grains have been ascertained by other experiments to consist of silver: then

as 110 : 78·4 :: 50 : 35; and
as 110 : 36 :: 50 : 16

100 × 51 = 151.

If, therefore, half the silver were combined with bromine and the other half with chlorine, the compound produced would amount to exactly 151 grains, which is found to correspond with the quantity actually obtained."

The following Table will show the quantity of precipitate that may be expected to result from the addition of nitrate of silver to 100 grains of a salt of sodium, according to the proportion of chloride and of bromide present:—

* Dr. Angus Smith, in his "Memoirs of Dalton," thus sums up the labours of this deep thinker:—This Dalton did. He gave the first idea of *atomic weights*. Under this head came Richter and Fischer's numbers. Richter, grappling with those numbers, never could obtain a rational theory from the phenomena. Dalton's plan explains these numbers with the greatest ease, and looks on such as a necessity of the fundamental law, instead of the beginning of the inquiry, as it was to them. It seems to me, then, that what happened historically happened also intellectually. Dalton had included his predecessors in his more extensive system. He had gone to the summit of the hill, and when coming down found proofs that they had been making good progress upwards. Higgins had gone at once to the top, as it appears to me, but took no heed to make the needful observations when he was up, or he found the prospect entirely obscured. We are compelled to put reciprocal proportions in a secondary position, as it seems to me it cannot be called a law, but one of the consequences of a law; and the evidence brought to support it, otherwise than empirically, presupposes some of the principles on which the general laws depend. It was by a careful mechanical juxtaposition of parts that Dalton arrived at the idea; it is eminently mechanical, and it is remarkable that all progressive views on the subject have been so. *He introduced proportional weights into the theory, and found it to agree with facts.* His is, therefore, the *quantitative atomic theory*."

ATOMIC WEIGHTS, EQUIVALENT, CHEMICAL EQUIVALENT, COMBINING WEIGHT, or PROPORTION, are the primal quantities in which the different objects of chemistry, simple or compound, combine with each other, referred to a common body taken as unity. Oxygen is assumed by some philosophers, and hydrogen by others, as the standard of comparison. Every chemical manufacturer should be thoroughly acquainted with the combining ratios which are, for the same two substances, not only definite, but often multiple; two great truths, upon which are founded, not merely the *rationale* of his operations, but also the means of modifying them to useful purposes. The discussion of the doctrine of atomic weights, or prime equivalents, belongs to pure chemistry; but several of its happiest applications are to be found in the processes of art, as pursued upon the largest scale.

The following propositions may be regarded as the laws regulating atomic combination:—

1. *The equivalents of elementary bodies represent the smallest proportions in which they enter into combination with each other.*

2. *The equivalent of a compound body is the sum of the equivalents of its elements.*

3. *Combination takes place, whether between elements or compounds, either in the proportions of their equivalents, or in multiples of these proportions, and never in submultiples.*

4. *The law of definite ana multiple proportion is, individual compounds always contain exactly the same proportions of their elements.* See EQUIVALENTS, CHEMICAL.

ATOMIC VOLUMES. Recently it has been assumed that the elements unite invariably in equal volumes—when in the gaseous state;—or, in other words, that the atoms of bodies have always the same volume. If this doctrine be maintained, it becomes necessary to alter the atomic weights or combining numbers of certain elements. For example, water contains two volumes of hydrogen to one of oxygen; but, according to the generally received idea, it consists of single atoms of each element; it is clear, therefore, that if we are to assume that the atoms of hydrogen and oxygen have the same volume, we must either halve the atomic weight of hydrogen or double that of oxygen.

Berzelius suggested that all the atomic weights should remain the same, except those of hydrogen, nitrogen, phosphorus, chlorine, bromine, and iodine, which should halve their present value. Gerhardt, on the other hand, adopts the more convenient practice of allowing hydrogen and its congeners to retain their present atomic weights, doubling those of oxygen, sulphur, tellurium, and carbon. See Watts' "Chemical Dictionary."

ATRAMENTUM. A product of the partial oxidation of iron pyrites, which is sometimes used in making ink.

ATROPINE. ($C^{34}H^{23}NO^6$) An exceedingly poisonous alkaloid, found in deadly nightshade (*Atropa Belladonna*) and in stramonium (*Datura Stramonium*). To the freshly prepared extract of belladonna add a strong solution of caustic potash, and well mix in a mortar. Digest the resulting mass at a temperature of 80° with benzole; separate the latter, and distil off the hydrocarbon in a retort on the water bath. The residue in the retort is to be treated with water acidulated with sulphuric acid; the acid solution is to be precipitated by carbonate of soda, and the resulting atropine may then be obtained pure by crystallisation from alcohol. Atropine is used in medicine for producing dilatation of the pupil of the eye. The smallest portion of a very dilute solution rubbed on the eyelid suffices to produce the result.

ATTALEA. *A. funifera* yields the Piassaba fibre used in Brazil for ropemaking, and in this country for the manufacture of bast-brooms. Another species of Attalea yields the coquilla nut much used in turnery. See COQUILLA.

Digitized by Google

ATTAR OF ROSES, more commonly, OTTO OF ROSES. An essential oil, obtained in India. Turkey, and Persia, from some of the finest varieties of roses. It is procured by distilling rose leaves with water, at as low a temperature as possible. It is said that this perfume is prepared also by exposing the rose leaves in water to the sun; but, from the fact that under the circumstances fermentation would be speedily established, it is not probable that this is a method often resorted to. By dry distillation from salt-water baths, no doubt the finest attar is obtained. This essential oil is only used as a perfume. Attar of roses is adulterated with spermaceti and with castor oil dissolved in strong alcohol.

This adulteration may be detected by putting a small drop of the otto of roses on a piece of clean writing paper; by agitation in the air, the volatile oil soon evaporates, leaving no stain if pure; if any fixed oil is present, a greasy spot is left on the paper.

ATTENUATION. Brewers and distillers employ this term to signify the weakening of saccharine worts during fermentation, by the conversion of the sugar into alcohol and carbonic acid.

AUGER. The auger is a tool for boring either wood or stone. The *single-lip auger* is forged as a half-round bar; it is then coiled into an open spiral, with the flat side outwards. The ordinary *screw auger* is forged as a parallelled blade of steel; it is twisted red-hot; the end terminates in a worm, by which the auger is gradually drawn into the work as in the gimlet; and the two angles, or lips, are sharpened to cut at the extreme ends, and a little up the sides also. The *American screw auger* has a cylindrical shaft, around which is brazed a single fin or rib; the end is filed into a worm, as usual, and immediately behind the worm a small diametrical mortise is formed for the reception of a detached cutter, which exactly resembles the chisel edge of the centre-bit. — *Holtzapffel.*

AUGITE (*αὐγή, brilliancy*). A sub-species of PYROXENE. The name is confined to the opaque and greenish-black varieties, common in basaltic and volcanic rocks, in which it forms an important constituent, but it is never found in granite. It has a base of magnesia and lime, with little or no iron, and usually no alumina.

AURUM MUSIVUM or MOSAICUM. MOSAIC GOLD.—For the preparation of Mosaic gold the following process is recommended by Woulfe. An amalgam of 2 parts of tin and 1 part of mercury is prepared in a hot crucible, and triturated with 1 part of sal ammoniac, and 1 part of flour of sulphur; the mixture is sublimed in a glass flask upon the sand bath. In breaking the flask after the operation, the sublimate is found to consist, superficially, of sal-ammoniac, then of a layer of cinnabar, and then of a layer of Mosaic gold.

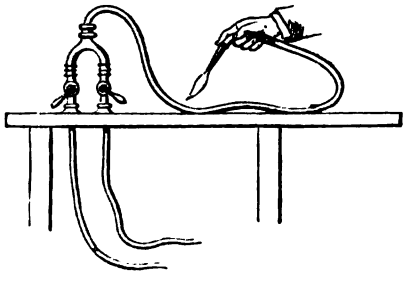
Bergman mentions a native *aurum musivum* from Siberia, containing tin, sulphur, and a small proportion of copper. Dr. John Davy gave the composition as—tin, 100; sulphur, 56·25; and berzelius as tin, 100; sulphur, 52·3. Mosaic gold is employed as a bronzing powder for plaster figures, and it is said to enter sometimes into the composition of aventurine.

AURATES. Crystalline compounds of the peroxide of gold.

AURIC ACID (*aurum*, gold.) A term sometimes used for the peroxide of gold.

AUTOGENOUS SOLDERING. A process of soldering by which metals are united, either by the ordinary solders or by lead, under the influence of a flame of hydrogen or of a mixture of hydrogen and common air.

152



The process of using air and hydrogen was invented in France, by the Count de Richemont. Hydrogen gas is contained in a gasometer, to which a flexible tube is connected, and air is urged, from a bellows worked by the foot, through another tube, and on to the blowpipe, where the hydrogen is ignited. By means of the flexible tubes the flame can be moved up and down the line of any joint, and the connecting medium melted. *Fig.* 152.

This process has been a good deal employed for plumbers' work, especially in our naval arsenals. In Devonport dockyard, the autogenic process has been largely used.

AUTOMATIC. A term employed to designate such economic arts as are carried on by self-acting machinery. The word is employed by the physiologist to express involuntary motions.

Digitized by Google

The term *automatic* is now applied to self-acting machinery, or such as has within itself the power of regulating entirely its own movements, although the moving force is derived from without; and to what pertains to such machinery; as *automatic* operations or improvements.—*Webster.*

The word "manufacture," in its etymological sense, means any system or objects of industry executed by the hands; but, in the vicissitude of language, it has now come to signify every extensive product of art which is made by machinery, with little or no aid of the human hand, so that the most perfect manufacture is that which dispenses entirely with manual labour. It is our modern cotton and flax mills that automatic operations are displayed to most advantage; for there the elemental power HEAT has been made to animate complex organs, imparting to forms of wood, iron, and brass, an agency of seeming intelligence. And as the philosophy of the fine arts, poetry, painting, and music, may be best studied in their individual master-pieces, so may the philosophy of manufactures in these its noblest creations.

The constant aim and effect of these automatic improvements in the arts are philanthropic, as they tend to relieve the workmen either from niceties of adjustment, which exhaust his mind and fatigue his eyes, or from painful repetition of effort, which distort and wear out his frame. A well arranged power-mill combines the operation of many work-people, adult and young, in tending with assiduous skill a system of productive machines continuously impelled by a central force. How vastly conducive to the commercial greatness of a nation, and the comforts of mankind, human industry can become when no longer proportioned in its results to muscular effort, which is by its nature fitful and capricious, but when made to consist in the task of guiding the work of mechanical fingers and arms regularly impelled, with equal precision and velocity, by some indefatigable physical agent, is apparent to every visitor of our cotton, flax, silk, wool, and machine factories. This great era in the useful arts is mainly due to the genius of Arkwright. Prior to the introduction of his system, manufactures where everywhere feeble and fluctuating in their development; shooting forth luxuriantly for a season, and again withering almost to the roots like annual plants. Their perennial growth then began, and attracted capital, in copious streams, to irrigate the rich domains of industry. When this new career commenced, about the year 1770, the annual consumption of cotton in British manufactures was under four millions of pounds weight, and that of the whole of Christendom was probably not more than ten millions. In 1850 the consumption in Great Britain and Ireland was about five hundred and eighty-eight millions of pounds, and that of Europe and the United States together, one thousand and ninety-two millions. In our spacious factory apartments the benignant power of Steam summons around him his myriads of willing menials, and assigns to each the regulated task, substituting, for painful muscular effort upon their part, the energies of his own gigantic arm, and demanding, in return, only attention and dexterity to correct such little aberrations as casually occur in his workmanship. Under his auspices, and in obedience to Arkwright's policy, magnificent edifices, surpassing far in number value, usefulness, and ingenuity of construction, the boasted monuments of Asiatic, Egyptian, and Roman despotism, have, within a short period, risen up in this kingdom, to show to what extent capital, industry, and science may augment the resources of a State while they ameliorate the condition of its citizens. Such is the automatic system, replete with prodigies in mechanics and political economy, which promises, in its future growth, to become the great minister of civilisation to the terraqueous globe, enabling this country, as its heart, to diffuse, along with its commerce, the life-blood of knowledge to myriads of people. Of these truths, the present work affords decisive evidence in almost every page.—*Watts' Dictionary of Chemistry.*

AUTOMATIC ARTS. Such arts or manufactures as are carried on by self-acting machinery.

AUTOMATON. (*αὐτόματος*—automatos—*self-moving.*) In the etymological sense, this word (self-working) signifies every mechanical construction which, by virtue of a latent intrinsic force, not obvious to common eyes, can carry on, for some time, certain movements more or less resembling the results of animal exertion, without the aid of external impulse. But the term automaton is, in common language, appropriated to those mechanical artifices in which the purposely concealed power is made to imitate the arbitrary or voluntary motions of living beings. Human figures, of this kind, are sometimes styled *Androides,* from the Greek term, *like a man.*

Although, from what has been said, clockwork is not properly placed under the head Automaton, it cannot be doubted that the art of making clocks, in its progressive improvement and extension, has given rise to the production of automata. The most of these, in their interior structure, as well as in the mode of applying the moving power, have a distinct analogy with clocks; and these automata are frequently mounted in connection with watchwork. Towards the end of the 13th century, several

Digitized by Google

tower clocks, such as those at Strasburg, Lubeck, Prague, Olmutz, had curious mechanisms attached to them. The most careful historical inquiry proves that automata, properly speaking, are not older than *wheel*-clocks; and that the more perfect structures of this kind are subsequent to the general introduction of *spring*-clocks. Many accounts of ancient automata, such as the flying pigeon of Archytas of Tarentum, appear to have been but poor mechanical contrivances. "The Pneumatics of Hero of Alexandria" have been rendered accessible to the English reader by the translation of Mr. Bennet Woodcroft. In this work will be found descriptions and drawings of several curious contrivances which must be included amongst automata. The following, amongst others, may be quoted:—

"An automaton which drinks at certain times only, on a liquid being presented to it.

"An automaton which may be made to drink at any time on a liquid being presented to it.

"An automaton which will drink any quantity which may be presented to it.

"An automaton, the head of which continues attached to the body after a knife has entered the head at one side, passed completely through it, and out at the other; which animal will drink immediately after the operation."

Beckmann informs us, quoting from Plato, that Dædalus made statutes which could not only walk, but which it was necessary to tie, in order that they might not move; and, on the authority of Aristotle, he speaks of a wooden Venus, and remarks that the secret of its motion consisted in quicksilver having been poured into it.

John Muller's iron flies (or, as he is sometimes called, Regiomontanus) and his eagle which flew towards the emperor Maximilian, in Nuremberg, in the year 1740, were probably exaggerated statements; for such master-pieces of art would form now, with every aid of our improved mechanisms, the most difficult of problems. The imitation of flying creatures is extremely difficult, for several reasons. There is very little space for the moving power, and the only material possessed of requisite strength being metal must have considerable weight. Two automata of the celebrated French mechanician, Vaucauson, first exhibited in the year 1736, have been greatly admired; namely a flute-player, five and a half feet high with its cubical pedestal, which played several airs upon the German flute; and that not by any interior tube-work, but through the actual blowing of air into the flute, the motion of the tongue, and the skilful stopping of the holes with the fingers; and a duck which imitated many motions of a natural kind in the most extraordinary manner. In 1738 M. Vaucauson published a memoir, approved of by the Academy of Sciences, in which he gave a full description of the machinery employed and of the principles of its construction. See Brewster's "Letters on Natural Magic." This artist has had many imitators, of whom the brothers Droz of Chaux de Fonds were the most distinguished. Several very beautiful clock mechanisms of theirs are known. One of them with a figure which draws; another playing on the piano; a third which writes, besides numerous other combined automata. Frederick Von Knauss completed a writing machine at Vienna, in the year 1760. It is now in the model cabinet of the Polytechnic Institute, and consists of a globe two feet in diameter, containing the mechanism upon which a figure seven inches high sits, and writes upon a sheet of paper fixed to a frame, whatever has been placed beforehand upon a regulating cylinder. At the end of every line, it raises its hand and moves it sideways, in order begin a new line.

Very complete automata have not been made of late years, because they are very expensive; and by soon satisfying curiosity, they cease to interest. Ingenious mechanicians find themselves better rewarded by directing their talents to the self-acting machinery of modern manufactures. We may notice here, however, the mechanical trumpeter of Mälzl, at Vienna, and a similar work of Kauffmann, at Dresden. In French Switzerland some artists continue to make minute automata which excite no little wonder; such as singing canary birds, with various movements of a natural kind; also little birds, sometimes hardly three quarters of an inch long, in snuff-boxes and watches of enamelled gold. Certain artificial figures which have been denominated automata, hardly deserve the name; since trick and confederacy are more or less concerned in their operation. It is likely, also, that the chess player of Von Kempelen, which excited so much wonder in the last century, had a concealed confederate. The very ingenious little figures of Tendler, father and son, which imitated English horsemen and rope dancers, constructed at Eisenerz, in Styria, are probably no more true automata than the *funtoccini*, or figures of puppets, which are exhibited in great perfection in many towns of Italy, especially at Rome.

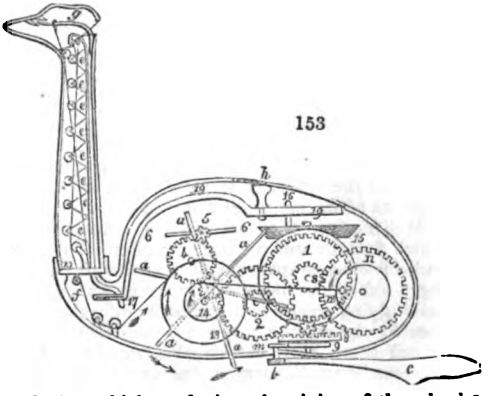
The moving power of almost all automata is a wound-up steel spring; because, in comparison with other means of giving motion, it takes up the smallest room, is easiest concealed and set a-going. Weights are seldom employed, and only in a par-

Digitized by Google

tial way. The employment of other moving powers is more limited; sometimes fine sand is made to fall on the circumference of a wheel, by which the rest of the mechanism is moved. For the same purpose water has been employed; and, when it is made to fall into an air-chamber, it causes sufficient wind to excite musical sounds in pipes. In particular cases quicksilver has been used, as, for example, in the Chinese tumblers, which is only a physical apparatus to illustrate the doctrine of the centre of gravity.

Figures are frequently constructed for playthings, which move by wheels hardly visible. An example of this simplest kind of automaton, which may be introduced here as illustrating the self-acting principles of manufactures, is shown in the figure.

Fig. 153 exhibits the outlines of an automaton, representing a swan, with suitably combined movements. The mechanism may be described, for the sake of clearness of explanation, under distinct heads. The first relates to the motion of the whole figure. By means of this part it swims upon the water, in directions changed from time to time without exterior agency. Another construction gives to the figure the faculty of bending its neck on several occasions, and, to such an extent, that it can plunge the bill and a portion of the head under water. Lastly, it is made to move its head and neck slowly from side to side.



153

On the barrel of the spring exterior to the usual ratchet wheel, there is a main-wheel, marked 1, which works into the pinion of the wheel 2. The wheel 2 moves a smaller one, shown merely in dotted lines, and on the long axis of the latter, at either end there is a rudder, or water-wheel, the paddles of which are denoted by the letter *a*. Both of these rudder-wheels extend through an oblong opening in the bottom of the figure down into the water. They turn in the direction of the arrow, and impart a straight-forward movement to the swan. The chamber in which these wheels revolve is made water tight, to prevent moisture being thrown upon the rest of the machinery. By the wheel 4, motion is conveyed to the fly-pinion 5; the fly itself, 6, serves to regulate the working of the whole apparatus, and it is provided with a stop bar, not shown in the engraving, to bring it to rest, or set it a-going at pleasure. Here, as we may imagine, the path pursued is rectilinear, when the rudder-wheels are made to work in a square direction. An oblique bar, seen only in section at *b*, movable about its middle point, carries at each end a web foot *c*, so that the direction of the bar *b*, and of both feet towards the rudder-wheels, determines the form of the path which the figure will describe. The change of direction of that oblique bar is effected without other agency. For this purpose the wheel 1 takes into the pinion 7, and this carries round the crown-wheel 8, which is fixed, with an eccentric disc 9, upon a common axis. While the crown-wheel moves in the direction of the arrow, it turns the smaller eccentric portion of the elliptic disc towards the lever *m*, which, pressed upon incessantly by its spring, assumes, by degrees, the position corresponding with the middle line of the figure, and afterwards an oblique position; then it goes back again, and reaches its first situation; consequently, through the reciprocal turning of the bar *h* and the swim-foot, is determined and varied the path which the swan must pursue. This construction is available with all automata which work by wheels; and it is obvious, that we may, by different forms of the disc 9, modify, at pleasure, the direction and the velocity of the turnings. If the disc is a circle, for instance, then the changes will take place less suddenly; if the disc is an outward and inward curvature, upon whose edge the end of the lever presses with a roller, the movement will take place in a serpentine line.

The neck is the part which requires the most careful workmanship. Its outward case must be flexible, and the neck itself should therefore be made of a tube of spiral wire, covered with leather, or with a feathered bird-skin. The double line in the interior, where we see the triangles *e e e*, denotes a steel spring made fast to the plate 10, which forms the bottom of the neck; it stands loose, and needs to be merely so strong as to keep the neck straight, or to bend it a little backwards. It should not

Digitized by Google

be equally thick in all points, but it should be weaker where the first graceful bend is to be made; and, in general, its stiffness ought to correspond to the curvature of the neck of this bird. The triangles *e* are made fast at their base to the front surface of the spring; in the points of each there is a slit, in the middle of which a movable roller is set, formed of a smoothly turned steel rod. A thin catgut string *f*, runs from the upper end of the spring, where it is fixed over all these rollers, and passes, through an aperture pierced in the middle of 10, into the inside of the rump. If the catgut be drawn straight back towards *f*, the spring, and consequently the neck, must obviously be bent, and so much the more, the more tightly *f* is pulled and is shortened in the hollow of the neck. How this is accomplished by the wheel-work will presently be shown. The wheel 11 receives its motion from the pinion *s*, connected with the main wheel 1. Upon 11 there is, moreover, the disc 12, to whose circumference a slender chain is fastened. When the wheel 11 turns in the direction of the arrow, the chain will be so much pulled onwards through the corresponding advance at the point at 12, till this point has come to the place opposite to its present situation, and, consequently, 11 must have performed half a revolution. The other end of the chain is hung in the groove of a very movable roller 14; and this will be turned immediately by the unwinding of the chain upon its axis. There turns, in connection with it, however, the large roller 13, in which the catgut *f* is fastened; and as this is pulled in the direction of the arrow, the neck will be bent until the wheel 11 has made a half revolution. Then the drag ceases again to act upon the chain and the catgut; the spring in the neck comes into play: it becomes straight, erects the neck of the animal, and turns the rollers 13 and 14 back into their first position.

The roller 13 is of considerable size, in order that through the slight motion of the roller 14, a sufficient length of the catgut way be wound off, and the requisite shortening of the neck may be effected; which results from the proportion of the diameters of the rollers 11, 13, 14. This part of the mechanism is attached as near to the side of the hollow body as possible, to make room for the interior parts, but particularly for the paddle-wheels. Since the catgut *f* must pass downwards on the middle from 10, it is necessary to incline it sideways and outwards towards 13, by means of some small rollers.

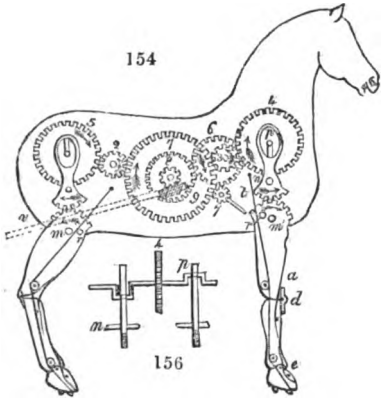
The head, constituting one piece with the neck, will be depressed by the complete flexure of this; and the bill, being turned downwards in front of the breast, will touch the surface of the water. The head will not be motionless; but it is joined on both sides, by a very movable hinge, with the light ring which forms the upper part of the clothing of the neck. A weak spring, *g*, also fastened to the end of the neck, tends to turn the head backwards; but in the present position it cannot do so, because a chain at *g*, whose other end is attached to the plate 10, keeps it on the stretch. On the bending of the neck, this chain becomes slack; the spring *h* comes into operation, and throws the head so far back that, in its natural position, it will reach the water.

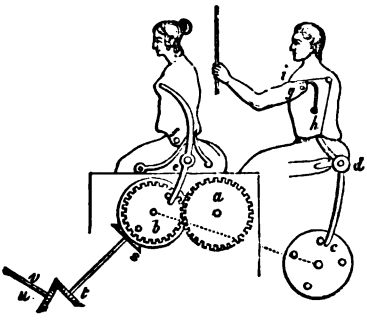
Finally, to render the turning of the head and neck practicable, the latter is not closely connected with the rump, while the plate 10 can turn in a cylindrical manner upon its axis, but cannot become loose outwardly. Moreover, there is upon the axis of the wheel 1, and behind it (shown merely as a circle in the engraving) a bevel wheel, which works into a second similar wheel, 15, so as to turn it in a horizontal direction. The pin, 16, of the last wheel works upon a two-armed lever, 19, movable round the point *h*, and this lever moves the neck by means of the pin 17. The shorter arm of the lever 19 has an oval aperture in which the pin 16 stands. As soon as this, in consequence of the movement of the bevel-wheel 15, comes into the dotted position, it pushes the oval ring outwards on its smaller diameter, and thereby turns the lever upon the point *h*, into the oblique direction shown by the dotted lines. The pin 16, having come on its way right opposite to its present position, sets the lever again straight. Then the lever, by the further progress of the pin in its circular path, is directed outwards to the opposite side; and, at last, when 15 has made an entire revolution, it is quite straight. The longer arm of the lever follows, of course, these alternating movements, so that it turns the neck upon its plate 10, by means of the pin 17; and, as 18 denotes the bill, this comes into the dotted position. It may be remarked, in conclusion, that the drawing of *fig.* 153 represents about half the size of which the automaton may be constructed, and that the body may be formed of thin sheet copper or brass.

Figs. 154, 155, 156, show the plan of a third automaton: a horse which moves its feet in a natural way, and draws a carriage with two figures sitting in it. The man appears to drive the horse with a whip; the woman bends forward from him in front. The four wheels of the carriage have no connection with the moving mechanism. In *fig.* 156, some parts are represented upon a larger scale. The wheel 1, in *fig.* 154, operates through the two carrier-wheels upon the wheels marked 4 and 5. By means of the axes of these two wheels, the feet are set in motion. The left fore-foot, *a*, then

Digitized by Google

the right hinder foot, move themselves backwards, and take hold of the ground with small tacks in their hoofs, while the two other legs are bent and raised, but no motion





of the body takes place. The carriage, however, with which the horse is connected, advances upon its wheels. By studying the mechanism of the foot, *a*, and the parts connected with it, we can readily understand the principles of the movement. The axis of wheel 4 is crank-shaped, on both sides, where it has to operate directly on the fore-feet; but for each foot it is bent in an opposite direction, as is obvious in the front view *fig.* 156. This crank, or, properly, its part furthest from the axis, serves instead of the pin 16 in the swan, and moves like it in an oval spot, *p*, *fig.* 154, a two-armed lever, which gives motion through tooth-work, but not as in the swan, by means of a second pin. This wheel-work renders the motion smoother. The above lever has its fulcrum at *n*, *fig.* 156, about which it turns alternately, to the one and the other side, by virtue of the rotation of the wheel 4. The toothed arch, or the half-wheel on the under side, lays hold of a shorter lever, in a similar arch, upon the upper joint of the foot, which is moved forwards and backwards upon the pivot *m*. In virtue of the motions in the direction of the arrow, the foot *a* will move itself first obliquely backwards, without bending, and the body will thereby bend itself forwards. When the right hand foot makes the same motion, both the other feet are raised and bent. The joints of the foot at *d* and *e* are formed of hinges, which are so constructed that they can yield no farther than is necessary at every oblique position of the foot. With the continued rotation of the wheel 4, the lever turns itself about *n*, in an inverted direction inwards, and impels the uppermost foot-joint forwards, so that it forms an acute angle with the body in front. The foot is now twice bent upon its joints. This takes place by the traction of the chain *t*, which is led over rollers (as the drawing shows) to the foot, and is there fastened. As its upper end has its fixed point in the interior of the body, it is therefore drawn by the eccentric pin *r* standing in the vicinity of *m*, and thus bends the foot at the hinges. If there were space for it, a roller would answer better than a pin. By the recedure of the uppermost joint into the first position, the tension of the chain *t* ceases again of itself, while the pin *r* removes from it, and the foot is again extended in a straight line by the small springs operating upon its two under parts, which were previously bent stiffly by the chain. By the aid of the figures with this explanation, it will be apparent that all the fore-feet have a similar construction, that the proper succession of motions will be effected through the toothed arcs, and the position of the cranks on the axis of the wheels 4 and 5, and hence the advance of the figure must follow. The wheel 6 puts the fly 7 in motion, by means of the small wheel marked 1; on the fixed points of the 4 chains, by means of a ratchet-wheel and a catch, the necessary tension will again be produced when the chains have been drawn out a little. There is sufficient room for a mechanism which could give motion to the head and ears, were it thought necessary.

The proper cause of the motions may now be explained. In *fig.* 155, *a* is a wheel connected with the wound-up spring, by which the motion of the two human figures, and also, if desired, that of the horse, may be effected. The axis of the wheel *b* carries a disc with pins, which operate upon the two-armed lever with its fulcrum *e*, and thus cause the bending of the upper part of one of the figures, which has a hinge at *f*. On the axis of that wheel there is a second disc, *c*, for giving motion to

Digitized by Google

the other figure, which, for the sake of clearness, is shown separate, although it should sit alongside of its fellow. On the upper end of the double-armed lever *d*, there is a cord whose other end is connected with the moving arm, in the situation *i*, and raises it whenever a pin in the disc presses the under part of the lever. A spring, *h*, brings the arm back into the original position, when a pin has passed from the lever, and has left it behind. The pins at *c* and *d* may be set at different distances from the middle of the disc, whereby the motions of the figures, by every contact of another pin, are varied, and are therefore not so uniform, and consequently more natural.

For the connection of both mechanisms, namely, the carriage with the horse, various arrangements may be adopted. Two separate traction springs should be employed; one at *a*, *fig.* 155, in the coach-seat; the other in the body of the horse. In the coach-seat at *b*, the fly with its pinion, as well as a ratchet-wheel, is necessary. By means of the shaft, the horse is placed in connection with the waggon. Or the following construction may be adopted.—To the axis of *b*, *fig.* 155, a bevel wheel is to be attached, and from this the motion is to be transmitted to the bottom of the carriage with the help of a second bevel wheel *s*, connected with a third bevel wheel *t*. This again turns the wheel *u*, whose long axis, *v*, goes to the middle of the horse's body, in an oblique direction, through the hollow shaft. This axis carries an endless screw, 9, *fig.* 154, with very oblique threads, which works into the little wheel 8, corresponding to the wheel 1, through an opening in the side of the horse, and in this way sets the mechanism of the horse a-going. With this construction of *fig.* 155, a spring of considerable strength is necessary, or if the height of the carriage-seat does not afford sufficient room, its breadth will answer for placing two weaker springs alongside of each other upon a common barrel.

AVENA. A genus of corn-bearing grasses. The *A. sativa* is the common oat.

AVENTURINE. (*Aventurine*, Fr.) A variety of quartz, which is minutely spangled throughout with yellow scales of mica; is known as *Aventurine quartz*. It is usually translucent, and of a grey, brown, or reddish-brown colour. There is also an *Aventurine felspar* (*Feldspath aventuriné*, Fr.). Commercially, in France and some other parts of Europe, the name of *Pierre de soleil* is given to the finest varieties of the felspar aventurine; some lapidaries, however, calling this stone by the name of *Aventurine orientale*. This aventurine occurs at Capa de Gata, in Spain; it has reddish and yellow internal reflections.

AVENTURINE GLASS has been manufactured on a large scale, for a long period, at the glass-works of Murano, near Venice. According to Wöhler's examination, aventurine glass owes its golden iridescence to a crystalline separation of metallic copper from the mass coloured brown by the peroxide of iron.

C. Karsten analysed the artificial aventurine from the glass manufactory of Bigaglia, in Venice, and found it to contain—

Silicic acid	67·3
Lime	9·0
Protoxide of iron	3·4
Binoxide of tin	2·3
Protoxide of lead	1·0
Metallic copper	4·0
Potash	5·3
Soda	7·0

These numbers agree in a remarkable manner with the results formerly obtained by Péligot, and may therefore be regarded as truly representing the composition of the glass.

AVENTURINE GLAZE for porcelain, exhibits a crystalline separation of green oxide of chromium from the brown ferruginous mass of the glaze producing a similar effect to the glass. This glaze is prepared as follows, according to A. Wächter:—

31	parts	of fine lixiviated dry porcelain earth from Halle,
43	„	dry quartz sand,
14	„	gypsum,
12	„	fragments of porcelain,

are stirred up with 300 parts of water, and by repeated straining through a linen sieve uniformly suspended in it, and intimately mixed. To this paste is added, under constant agitation, and one after the other, aqueous solutions of

19	parts	bichromate of potash,
100	„	protosulphate of iron,
47	„	acetate of lead,

Digitized by Google

and then so much solution of ammonia that the iron is completely separated. The salts of potash and ammonia are removed by frequent decantation with spring water.

The baked porcelain vessels are dipped into the pasty mixture obtained as above described, in the same manner as with other glazes, and then fired in the porcelain furnace. After this they are covered with a brown glaze, which in reflected light appears to be filled with a countless number of light gold spangles.

A thin fragment of the glaze appears, under the microscope, by transmitted light, as a clear brownish glass, in which numerous transparent green six-sided prisms of oxide of chromium, and some brownish crystals, probably of oxide of chromium and peroxide of iron, are suspended. The oxide of chromium, therefore, separates, on the slow cooling of the glaze in the porcelain furnace, from the substance of the glaze — a silicate of potash, lime, and alumina, saturated with the peroxide of iron — and shines through the brownish mass with a golden colour. When the aventurine glaze is mixed with an equal amount of colourless porcelain glaze, the glassy mass no longer has a brown colour after the burning, but a light greenish-grey, and the eliminated crystalline spangles likewise exhibit in reflected light their natural green colour.

AVENA SATIVA. The common oat (*which see*).

AVERRUNCATOR. A pair of pruning shears, which, on being mounted on a pole some ten feet long, and actuated by a string of catgut, can be used for pruning at a considerable distance above the head.

AVOCADO PEAR OIL. An oil obtained from the oleaginous fruit the Avocado pear-tree (*Laurus Persea*), a native of Trinidad. A portion of this oil having been submitted to Dr. Hofmann by the Governor of Trinidad, he reported on its character:— "According to my present experience, the oil of the Avocado pear is less valuable as a lubricating material. To make it fit for the higher classes of machinery, its mucilaginous constituents must be removed by the same refining process requisite for its adaptation in illuminating purposes.

"On the other hand, the oil of the Avocado pear is very applicable for the production of good soap. I have the honour of transmitting to your Excellency specimens prepared with the oil: the smaller one, which possesses a yellow colour, is prepared with the oil in its original condition; the larger one is made with a portion of oil which had previously been bleached by chlorine. From this specimen it is obvious that the oil, although poor in stearine, nevertheless furnishes a soap which is tolerably hard and solid. I have even now no hesitation in stating that, for the purposes of the soap-maker, the oil of the Avocado pear will have, at least, the same value as palm oil."

AXE. A tool much used by carpenters for cleaving and roughly fashioning blocks of wood. It is a thin iron wedge with an oblong steel edge, parallel to which, in the short base, is a hole for receiving and holding fast the end of a strong wooden handle.

AXE STONE. A sub-species of *jade* found in Corsica, Saxony, and on the banks of the Amazon. It is a silicate of magnesia and alumina coloured by oxide of chromium. See JADE.

AXINITE. A silica-borate of alumina and lime. It is so named from the axe-like bevelling of its lateral edges. It is found in St. Just in Cornwall, in France, Norway, and Saxony.

AXLES, of carriages. See WHEEL CARRIAGES.

AXUNGE. Hog's lard. See FAT and OILS.

AYR STONE, called also Scotch stone and snake stone, is much in request as a polishing stone for marble and for copper plates. These stones are always kept damp, or even wet, to prevent their becoming hard.

The harder varieties of Ayr stone are now employed as whetstones.

AZALÏNE. See ANILINE RED.

AZIMUTH COMPASS. The azimuth compass is used chiefly to note the actual magnetic azimuth, or that arch of the horizon intercepted between the azimuth, or vertical circle passing through the centre of any heavenly body and the magnetic meridian.

The card of the azimuth compass is subdivided into exact degrees, minutes, and seconds. To the box is fixed two "sights," through which the sun or a star may be viewed. The position into which the index of the sights must be turned to see it, will indicate on the card the azimuth of the star. When the observations are intended to be exact, telescopes take the place of the sights. By this instrument we note the actual magnetic azimuth; and, as we know the azimuth calculated from the N. and S. line, the variation of the needle is readily found.

AZOBENZIDE. ($C^{24}H^{10}N^2$) A peculiar substance formed by acting with an alcoholic solution of potash upon nitrobenzole, or, as it is sometimes called, artificial oil of bitter almonds. (See NITROBENZOLE.) If nitrobenzole, dissolved in alcohol, with the addition of solid potash, be distilled, a complex and by no means well understood reaction occurs. The azobenzide distils over mixed with aniline. The fluid treated with hydrochloric acid, to dissolve the aniline, is passed through a wet filter; the aniline salt passes through, leaving the azobenzide as a red oil, which in a few moments solidifies into a mass of rich golden-brown crystals of considerable size, even when working on a very small quantity. The alcohol enters into the reaction, and oxalic acid is formed, which unites with the potash. Four equivalents of nitrobenzole and two equivalents of alcohol appear to yield one equivalent of azobenzide, two equivalents of aniline, four equivalents of oxalic acid, and eight equivalents of water; or, in symbols —

$$\underbrace{4C^{12}H^5NO^4}_{\text{Nitrobenzole.}} + \underbrace{2C^4H^6O^2}_{\text{Alcohol.}} = \underbrace{C^{24}H^{10}N^2}_{\text{Azobenzide.}} + \underbrace{2C^{12}H^7N}_{\text{Aniline.}} + \underbrace{4C^2O^3}_{\text{Oxalic acid.}} + \underbrace{8HO}_{}.$$

Azobenzide yields numerous derivations. With fuming nitric acid it gives two nitro compounds; viz., nitroazobenzide and binitroazobenzide. Azobenzide, treated with sulphide of ammonium, yields an alkaloid called benzidine, $C^{24}H^{12}N^2$.—C. G. W.

AZOBENZOIDE. When bitter almonds are distilled, *per descensum*, an oil is obtained; if the latter be treated with ammonia, and the substance thus formed be treated with ether, a white powder remains, which is probably impure hydrobenzamide.—C. G. W. See Watts' "Chemical Dictionary"

AZOBENZOYLE. A substance formed simultaneously with hydrobenzamide and benzydramide, when oil of bitter almonds is treated with ammonia.—C. G. W.

AZOTE. See NITROGEN.

AZOTIZED, said of certain vegetable substances, which, as containing azote, were supposed at one time to partake, in some measure, of the animal nature. The vegetable products, indigo, cafeine, gluten, and many others, contain abundance of azote.

AZURE. This term was applied by Pliny to the blues of the ancients. "Cæruleum, or azure, is of three kinds: the Egyptian (artificial); the Scythian (natural), which is inferior; the Cyprian, the best."—(*Theophrastus*, also *Pliny*.) Girardin, writing of the ancient colours, says, "This *azure*, which has thus endured above 1700 years, may be cheaply and easily made thus: 15 parts, *by weight*, of carbonate of soda, 20 parts of opaque flints, and 3 parts of copper filings, are strongly heated for two hours, and the mixture will result in a fine deep sky-blue." The Egyptian blue, or Alexandrian frit, is a pulverised blue glass; it was once thought to contain cobalt, but all analyses prove it to be a silicate of copper.

The term Azure has been applied to smalts. See COBALT, SMALT, and ULTRAMARINE.

AZURINE. See ANALINE BLUE, and ANALINE GREEN.

AZURITE. This term has been applied to several blue minerals, which have little in common. Beudant and Dana use it to siguify the blue carbonate of copper — now termed Chessylite by Brook and Miller, from its occurring in fine crystalline forms at Chessy, near Lyons; hence commonly called *Chessy copper*.

Azurite is also applied to the *Lazulite* of Dana; which is again called *Azure stone* and blue spar by others.

The same term is also given to the Lapis lazuli, from which ultramarine is obtained.

This want of agreement between mineralogists — leading them to adopt names independent one of the other (names frequently taken from some locality in which the writer knows the mineral to be found) — produces great confusion, and retards the progress of knowledge.

B

BABLAH. The rind or shell which surrounds the fruit of the *Mimosa cineraria*; it comes from the East Indies, and also from Senegal, under the name of Neb-neb. It contains gallic acid, tannin, a red colouring matter, and an azotized substance; but the proportion of tannin is smaller than in sumach and galls, in reference to that of gallic acid, which is considerable in the bablah. It has been used in dyeing cotton, for producing various shades of drab, as a substitute for the more expensive astringent dye-stuffs.

BACK. A mining term. The back of a mineral lode is that part which is nearest the surface. The back of a level is the ground between it and the level above it.

Digitized by Google

BACK. A brewer's utensil—the reservoir for receiving the wort.

BABUL-GUM. An inferior gum from the Babul tree, *Acacia Arabica* (*Wild*) growing in Bengal. This is sometimes called Bengal gum.

BADGER. Meles (*Blairean*, Fr., *Dachs*, Germ.) A genus of carnivorous animals belonging to the family *Mustelidæ*. *M. Taxus*, the common badger, inhabits the northern parts of Europe and Asia. The hide of the badger when properly dressed, makes the best pistol furniture; the hair is valuable for making brushes to soften the shades in painting, and is used for the best class of shaving brushes; the hind quarters, when salted and smoked, make excellent hams.

BAGASSE. The sugar-cane, in its dry crushed state, much employed for fuel in the colonial sugar-houses.

BAIN-MARIE. A vessel of water in which saucepans, &c., are placed to warm food.

BAIZE. A coarse woollen stuff with a long nap, sometimes friezed on one side.

BAKERS' SALT. The sesquicarbonate of ammonia, so called because it is often used as a substitute for yeast in bread and pastry.

BAKING. (*Cuire*, Fr.; *Backen*, Germ.) The exposure of any body to such a heat as will dry and consolidate its parts without wasting them. Thus wood, pottery, and porcelain, are baked, as well as bread and meat. See BISCUIT; BREAD.

BAL. An ancient Cornish miner's term for a mine.

BALACHONG. An article of food much used in the Eastern Archipelago, consisting of fish and shrimps pounded together.

BALÆNA. The Greenland Whale. See WHALEBONE.

BALANCE. To conduct arts and manufactures with judgment, recourse must be had to a balance. Experience proves that all material bodies existing upon the surface of the earth are constantly solicited by a force which tends to bring them to its centre, and that they actually fall towards it when they are free to move. This force is called gravity. Though the bodies be not free, the effort of gravity is still sensible, and the resultant of all the actions which it exercises upon their material points constitutes what is popularly called their *weight*. These weights are, therefore, forces which may be compared together, and by means of machines may be made to correspond or be counterpoised.

To discover whether two weights be equal, we must oppose them to each other in a machine where they act in a similar manner, and then see if they maintain an equilibrium; for example, we fulfil this condition if we suspend them at the two extremities of a lever supported at its centre, and whose arms are equal. Such is the general idea of a balance. The beam of a good balance ought to be a bar or double cone of metal, of such strength as to secure perfect inflexibility under any load which may be fitly applied to its extremities. Its arms should be quite equal in weight and length upon each side of its point of suspension; and this point should be placed in a vertical line over the centre of gravity; and the less distant it is from it, the more delicate will be the balance. Were it placed exactly in that centre, the beam would not spontaneously recover the horizontal position when it was once removed from it. To render its indications more readily commensurable, a slender rod or needle is fixed to it, at right angles, in the line passing through its centres of gravity and suspension. The point, or rather edge, of suspension, is made of perfectly hard steel, and turns upon a bed of the same. For common uses the arms of a balance can be made sufficiently equal to give satisfactory results; but, for the more refined purposes of science, that equality should never be presumed nor trusted to; and, fortunately, exact weighing is quite independent of that equality. To weigh a body is to determine how many times the weight of that body contains another species of known weight, as of grains or pounds, for example. In order to find it out, let us place the substance, suppose a piece of gold, in the left hand scale of the balance; counterpoise it with sand or shot in the other, till the index needle be truly vertical, or stand in the middle of its scale, proving the beam to be horizontal. Now remove gently the piece of gold, and substitute in its place standard multiple weights of any graduation, English or French, until the needle again resumes the vertical position, or until its oscillations upon either side of the zero point are equal. These weights will represent precisely the weight of the gold, since they are placed in the same circumstances with it, and make the same equilibrium with the weight laid in the other scale.

This method of weighing is obviously independent of the unequal length as well as the unequal weight of the arms of the beam. For its perfection two requisites only are indispensable. The first is that the points of suspension should be rigorously the same in the two operations; for the power of a given weight to turn the beam being unequal, accordingly as we place it at different distances from the centre of suspension, did that point vary in the two consecutive weighings, we should require to employ, in the second, a different weight from that of the piece of gold, in order to form an equilibrium with

Digitized by Google

the sand or shot originally put in the opposite scale; and as there is nothing to indicate such inequality in the states of the beam, great errors would result from it. The best mode of securing against such inequality is to suspend the cords of the scales from sharp-edged rings, upon knife edges, at the ends of the beam, both made of steel so hard tempered as to be incapable of indentation. The second condition is, that the balance should be very sensible—that is, when in equilibrium and loaded, it may be disturbed, and its needle may oscillate, by the smallest weight put into either of the scales. This sensibility depends solely upon the centre of suspension; and it will be the more perfect the less friction there is between that *knife-edge* surface and the plane which supports it. Both should therefore be as hard and highly polished as possible; and should not be suffered to press against each other, except at the time of weighing. Every delicate balance of moderate size, moreover, should be suspended within a glass case, to protect it from the agitations of the air, and the corroding influence of the weather. In some balances a ball is placed upon the index or needle, (whether that index stand above or below the beam,) which may be made to approach or recede from the beam by a fine-threaded screw, with the effect of varying the centre of gravity relatively to the point of suspension, and thereby increasing, at will, either the sensibility or the stability of the balance. The greater the length of the arms, the less distant the centre of gravity is beneath the centre of suspension, the better polished its central knife-edge of 30°, the lighter the whole balance, and the less it is loaded, the greater will be its sensibility. In all cases the arms must be quite inflexible. A balance made by Ramsden for the Royal Society is capable of weighing ten pounds, and turns with one hundredth of a grain, which is the seven-millionth part of the weight. In pointing out this balance, Dr. Wollaston remarked it was so delicate, that Mr. Pond, then Astronomer-Royal, when making some observations with it, found its indications affected by his relative position before it, although it was enclosed in a glass case. When he stood opposite the right arm, that end of the beam preponderated, in consequence of its becoming expanded by the radiation of heat from his body; and when he stood opposite the left arm, he made this preponderate in its turn. It is probable that Mr. Pond had previously adjusted the centres of gravity and suspension so near to each other as to give the balance its maximum sensibility consistent with stability. Were these centres made to coincide, the beam, when the weights are equal, would rest in any position, and the addition of the smallest weight would overset the balance, and place the beam in a vertical position, from which it would have no tendency to return. The sensibility in this case would be the greatest possible; but the other two requisites of level and stability would be entirely lost. The case would be even worse if the centre of gravity were higher than the centre of suspension, as the balance when deranged, if free, would make a revolution of no less than a semi-circle. — *Ure.*

BALANCE FOR WEIGHING COIN, introduced at the Bank of England in the year 1841, requires an especial notice.

Mr. William Cotton, then Deputy-Governor, and during the two succeeding years Governor of the Bank, had long regarded the mode of weighing by common hand-balances with dissatisfaction, on account of its injurious effect upon the "teller," or weigher, owing to the straining of the optic nerve by constant watching of the beam indicator, and the necessity of reducing the functions of the mind to the narrow office of influencing a few constantly repeated actions. Such monotonous labour could not be endured for hours together without moments of forgetfulness resulting in errors. Errors more constant, although less in amount, were found to be due to the rapid wearing of the knife-edges of the beam; currents of air also acting upon the pans produced undesired results; and even the breath of the "teller" sometimes turned the scale; so that in hand-weighing, the errors not unfrequently amounted to $\frac{1}{3}$rd, and even $\frac{1}{4}$ grain. At the very best, the hand-scale working at the rate of 3000 per six hours could not indicate nearer than $\frac{1}{8}$th grain.

Upon taking into consideration the inconveniences and defects of the hand-weighing system, Mr. Cotton conceived the idea that it might be superseded by a machine defended from external influences, and contrived so as to weigh coins as fast as by hand, and within the fourth of a grain. He subsequently communicated his plan to Mr. David Napier, of York Road, Lambeth, engineer, who undertook the construction of an experimental machine. Its capabilities were tested and reported upon by Mr. William Miller, of the Bank. The result was most satisfactory; more "automaton balances" were ordered; and from time to time further additions have been made, so that at present there are ten in daily operation at the Bank of England. But it was not without a struggle that the time-hallowed institution of tellers passed away. There were interests opposed to the introduction of improved, more ready, and less expensive methods; and it required all Mr. Cotton's energy of character, the influence of his intelligence in mechanics, as well as that arising from his position in

Digitized by Google

the Direction, to obtain the adoption of an invention by which a very large annual saving has been effected.

The mechanical adaptation of the principles involved in the Automaton Balance, as contrived by Mr. Napier, may be shortly explained:—The weighing beam, of steel, is forked at the ends, each extremity forming a knife-edge; and in the centre the fulcrum knife-edge extends on each side of the plate of the beam, and rests in hollows cut in a bowed cross-bar fixed to the under side of a rectangular brass plate, about 12 inches square, which is supported at the corners by columns fixed to a cast-iron table raised a convenient height on a stand of the same metal. To form a complete enclosing case, plates of metal or glass are slid into grooves down the columns. When the beam is resting with its centre knife-edge in the hollows of the cross-bar just referred to, its upper part is nearly on a level with the under-side of the brass plate, in which a long slot is made, so that the beam can be taken out when the feeding slide-box, and its plate, which covers this slot, are removed. On the top of the covering plate of the feeding slide a tube hopper is placed, and a hole in the plate communicates with the slide; another hole is pierced in the same plate exactly over one end of the beam, upon the knife-edges of which a long rod is suspended by hollows formed in a cross-bar close to its upper end, where the weighing platform is fitted. A rod is also suspended at the other end of the beam in a similar manner; but instead of a weighing plate, it has a knob at top, which, when the beam is horizontal, comes into contact with an adjustable agate point. The lower end of this pendant rod is stirrup-shaped, for holding the counterpoise. Two displacing slides are provided, one on each side of the feeding slide, and at right angles to each other; and a gripping apparatus is fixed to the under side of the brass top plate, arranged so as to hold the pendant on which the scale-plate is fitted during the change of the coin. A dipping finger is also attached to the frame of the gripping apparatus, its end passing into a small slot in the pendant rod, and acting upon a knife-edge at the lower end of the slot. There are four shafts crossing the machine; the one through which the power is applied is placed low and at the centre, and carries a pinion which gears with a wheel of twice its diameter on a shaft above; this wheel gears with two similar wheels fixed to shafts on each side of the centre. Cams for acting upon the feeding slide, through the medium of a rocking frame, are carried by the shaft placed at the end of the machine where the counterpoise hangs, and the other two shafts on the same level bear cams for working the gripping apparatus, the dipping finger, and the displacing slides.

Having described, as clearly and as popularly as we can, the general features of the mechanism, we will proceed to indicate its manner of action. Suppose, then, the hopper filled, and a hollow inclined plane about two feet long, which has been added to the hopper by the inventive genius of one of the gentlemen in the weighing-room, also loaded its whole length with the pieces to be weighed, the machine is set in motion, and the feeding slide pushes the lowest piece forward on to the weighing plate, the grippers meantime holding fast by the neck of the pendant, so as to keep the plate perfectly steady; the dipping-finger is also at its lowest position, and resting upon the knife-edge at the bottom of the slot in the pendant rod, thus keeping the beam horizontal, and the knob on the counterpoise pendant, in contact with the agate point already mentioned. When the coin is fairly placed on the weighing-plate, the grippers let go their hold of the pendant rod, and the dipping-finger is raised by its cam; if then the coin is too light, the coin end of the beam will rise along with the dipping-finger, and the counterpoise end will descend; if heavy, the beam will remain without motion, the agate point preventing it. As soon as the dipping-finger attains the proper height, and thus has allowed sufficient time for the weight of the coin to be decided, the grippers close and hold the pendant, and consequently the scale or weighing-plate, at the high level, if the coin has proved light, and been raised by the excess of weight in the counterpoise; and at the low or original level, if the coin has proved heavy. One of the displacing slides now comes forward and passes under the coin, if it is light, and therefore raised to the high level; but knocks it off, if remaining on the low level, into the "heavy" box. The other displacing slide then advances. This strikes higher than the first, and removes the light piece which the other has missed, into the receptacle for the light coin. During these operations the feeding-slide has brought forward another coin, and the process just described is repeated. The attendant is only required to replenish the inclined plane at intervals, and remove the assorted coin from the boxes. The perfection of the workmanship, and the harmony of the various actions of the machine, will be best appreciated from the fact, that 25 pieces are weighed per minute to the fineness of $\frac{1}{100}$th of a grain. This combination of great speed and accuracy would not have been possible with a beam made in the ordinary way, having the centre of gravity below the centre of action; and it was pronounced to be so by the late Mr. Clement, the

Digitized by Google

constructor of Mr. Babbage's Calculating Machine. But Mr. Napier overcame the difficulty by raising the centre of gravity so as to coincide with the centre of action, which gave it much greater sensibility; and he provided the dipping-finger, to bring the beam to a horizontal position after each weighing, instead of an influencing weight in the beam itself.

The wear and tear of these machines is found to be very small indeed; those supplied in 1842 and 1843, and in daily use ever since, weigh with the same accuracy as at first, although they may be said to have cost nothing for repairs. The principal cause of this long-continued perfection is that the beam does not oscillate, unless the coin is light, and even then the space passed through does not exceed the thickness of the coin.

In 1851, when the Moneyers were no longer *masters* of the Royal Mint, and the new authorities began to regard the process of weighing the coin in detail by hand as a laborious, expensive, and inaccurate method, the firm of Napier and Son, at an interview with Sir John Herschel, the Master, and Captain Harness, the Deputy-Master, received an order for five machines, to be designed to suit the requirements of the Mint, which involved a complete change in the mechanical arrangement of the machine as used at the Bank, it being necessary to divide the "blanks," or pieces before they are struck, into three classes: "too light," "too heavy," and "medium," or those varying between certain given limits. It would occupy too much space to attempt a description of the mechanical disposition of this machine, and it could not be satisfactorily accomplished without the aid of drawings; let it suffice, then, to say that the displacing-slides are removed, and a long vibrating conducting-tube receives the blanks as they are in turn pushed off the weighing-plate by the on-coming blanks; but, according to the weight of the blank, so the lower end of the tube is found to be opposite to one of three openings leading into three boxes. The tube is sustained in its proper position, during the descent of the blank last weighed through it, by a stop-finger, the height of which is regulated by a dipping-finger, which comes down upon a knife-edge at the lower end of a slot in the pendant-rod just when the grippers have laid hold of the rod after the weighing is finished; this finger thus ascertains the level which the knife-edge has attained, and as it brings down the stop-finger with it, the guide-tube, which is furnished with three rests, as steps in a stair, vibrates against the stop-finger, one of the three steps coming in contact with it, according to the level of the stop-finger; and the end of the guide-tube takes its place opposite the channel leading to the box in which the blank should be found. The counterpoise employed is less than the true standard weight, by the quantity which may be allowed as the limit in that direction; and in case a blank is too heavy, not only is the counterpoise raised, but a small weight, equal to the range allowed between the "too light" and "too heavy," is raised also; this small weight comes to rest on supports provided for it when the beam is horizontal, and is only disturbed by a *too heavy* blank.

These machines have proved even more accurate and rapid than those made for the Bank; and Professor Graham, the present master, amongst the improvements introduced by him into the system of the Mint, has added to the number, and dispensed entirely with the hand weighing. It is said that the saving accruing from this change alone amounts to nearly 2000*l.* per annum.

BALAS RUBY. The name applied to *rose-red* varieties of spinel. See RUBY.

BALE. A package of silk, linen, or woollen, is so called.

BALLISTIC PENDULUM. An instrument for measuring the force of cannon-balls. The ballista was an instrument used by the ancients to throw darts, &c. The ballistic pendulum derives its name from this: it consists of an iron cylinder, closed at one end, suspended as a pendulum. A ball being fired into the open end, deflects the pendulum according to the force of the blow received from the ball, thus measuring its power.

BALLOON. In France, a quantity of glass. Of *white glass*, 25 bundles of six plates each; of *coloured glass*, 12½ bundles of three plates each are called balloons.

BALLOON, AIR. A varnished silk or other bag filled with gas, or warm air, which, being specifically lighter than the atmosphere, ascends in it. Numerous attempts have been made to bring air balloons under the control of the aëronaut, so as to guide them across the currents of the atmosphere; but all of these have proved unsuccessful, the balloon and its voyagers having always moved with the aërial current, in spite of the mechanical appliances which have been adopted.

BALSAM. (*Baume*, Fr.; *Balsame*, Germ.) A native compound of ethereal or essential oils, with resin, and frequently benzoic acid. Most balsams have the consistence of honey; but a few are solid, or become so by keeping. They flow either spontaneously, or by incisions made from trees and shrubs in tropical climates. They have peculiar and sometimes powerful smells, aromatic hot tastes, but lose their odori-

Digitized by Google

ferous properties by long exposure to the air. They are insoluble in water; soluble to a considerable degree, in ether; and completely in alcohol. When distilled with water, ethereal oil comes over, and resin remains in the retort.

BALSAM, CANADA. See CANADA BALSAM.

BALSAM COPAIVA, or CAPIVI, or COPAIBA. (*Baume de Copahu*, Fr.; *Kopaiva Balsam*, Germ.) *Copaiva balsam*, balsam of copahu, or capivi, is obtained from incisions made in the trunk of the *Copaifera officinalis*, a tree which grows in Brazil and Cayenne. It is also very frequently obtained from the *C. Multijuga*, *C. Langodorfi*, and *C. Coriacea*. It is pale yellow, semi-liquid, clear and transparent, has a bitter, sharp, hot taste; a penetrating disagreeable smell; a specific gravity of from 0·950 to 0·996. It dissolves in absolute alcohol, and partially in spirits of wine, and forms with alkalis crystalline compounds. It consists of 45·59 ethereous oil, 52·75 of a yellow brittle resin, and 1·66 of a brown viscid resin. The oil contains no oxygen, has a composition like oil of turpentine, dissolves caoutchouc (according to Durand), but becomes oxidised, in the air, into a peculiar species of resin.

This substance is extensively used in medicine. It was formerly often adulterated; some unctuous oil being mixed with it, but as this is easily discovered by its insolubility in alcohol, castor oil has since been used. The presence of this cheaper oil may be detected,—1, by agitating the balsam with a solution of caustic soda, and setting the mixture aside to repose, when the balsam will come to float clear on the top, and leave a soapy thick magma of the oil below; 2, when the balsam is boiled with water, in a thin film, for some hours, it will become a brittle resin on cooling, but it will remain viscid if mixed with castor oil; 3, if a drop of the oil on white paper be held over a lamp, at a proper distance, its volatile oil will evaporate and leave the brittle resin, without causing any stain around, which the presence of oil will produce; 4, when three drops of the balsam are poured into a watch-glass, alongside of one drop of sulphuric acid, it becomes yellow at the point of contact, and altogether of a saffron hue when stirred about with a glass rod; but if sophisticated with castor oil, the mixture soon becomes nearly colourless, like white honey, though after some time the acid blackens the whole in either case; 5, if 3 parts in bulk of the balsam be mixed with one of good water of ammonia (of 0·970 specific gravity) in a glass tube, it will form a transparent solution if it be pure, but will form a white liniment if it contains castor oil; 6, if the balsam be triturated with a little of the common magnesia alba, it will form a clear solution, from which acids dissolve out the magnesia, and leave the oil transparent if it be pure, but opaque if it be adulterated. When turpentine is employed to falsify the balsam, the fraud is detected by the smell on heating the compound.

This balsam is used in the manufacture of some varieties of *tracing paper*; and many lacquers and varnishes have the balsam of copaiva as one of their constituents.

Of Balsam Capivi, we imported in 1864:—

BALSAM, MECCA. (*Baume de la Mecque*, *Baume du Judée*, Fr.) *Mecca balsam*, or *opobalsam*, or *Balm of Gilead*, is obtained both by incisions in, and by boiling, the branches and leaves of the *Amyris opobalsamum*, a shrub which grows in Arabia Felix and Egypt. When fresh it is turbid and whitish, becomes by degrees transparent, yellow, thickish, and eventually solid. Its smell is peculiar, but agreeable; it tastes bitter and spicy; does not dissolve completely in hot spirit of wine, and contains 10 per cent. of ethereal oil of the specific gravity 0·876.

BALSAM OF PERU. (*Baume du Pérou*, Fr.; *Peruvianischer Balsam*, Germ.) *Balsam of Peru* is extracted from the *Myroxylon Peruiferum*, a tree which grows in Peru, Mexico, &c.; sometimes by incision, and sometimes by evaporating the decoction of the bark and branches of the tree. The former kind is very rare, and is imported in the husk of the cocoa-nut, whence it is called balsam *en coque*. It is brown, transparent only in thin layers of the consistence of thick turpentine, an agreeable smell, an acrid and bitter taste; formed of two matters, the one liquid, the other granular, and somewhat crystalline In 100 parts, it contains 12 of benzoic acid, 88 of resin, with traces of a volatile oil.

The second sort, the *black* balsam of Peru, is much more common than the preceding; translucent, of the consistence of well-boiled syrup, very deep red-brown colour, an almost intolerably acrid and bitter taste, and a stronger smell than the other

Digitized by Google

balsam. Stoltze regards it as formed of 69 parts of a peculiar oil, 20·7 of a resin little soluble in alcohol, of 6·4 of benzoic acid, of 0·6 of extractive matter, and 0·9 of water.

The celebrated *Pomade Divine*, which was a few years since very celebrated, contained a considerable quantity of the balsam of Peru. One of the best recipes for its preparation was the following:—

Fine olive oil	18 ozs.
Balsam of Peru	1 oz.
Oris root	6 drachms.
Strained storax	1 drachm.

This, with some bruised nutmegs and cinnamon, was macerated in a water-bath for three hours, and then filtered.

A French authority states that, dissolved in four times its weight of alcohol, and spread upon sarsenet already covered with a layer of isinglass, it formed the *taffetas d'Angleterre*.

One thousand parts of good balsam should, by its benzoic acid, saturate 75 parts of crystallised carbonate of soda. It is employed as a perfume for pomatums, tinctures, lozenges, sealing-wax, and for chocolate and *liqueurs*, instead of vanilla, when this happens to be very dear.

M. Victor le Nouvel, who has been engaged in collecting this balsam since 1836, gives the following as the process used by the Indians to obtain it. An incision is made into the tree of about two or three inches broad, and three to four inches long. They raise the bark from the wood and apply cotton rags to it; a fire being lighted round the tree to liquefy the balsam. Fresh incisions are made higher and higher up the tree, till the cotton rags are quite saturated. It takes from ten to twelve days to effect this. The rags are next boiled, and when the liquor is cold, the balsam collects below.—*Pereira's Materia Medica.*

Balsam of Peru has been for some years exported from the state of Salvador (in 1855, 22,804 lbs., valued at 19,827 dollars). On the coast of Chiquimulilla (Guatemala) there are many trees of the description that yield the balsam, but hitherto it has not attracted the attention of the people to collect it.—*Consul's Report.*

The Balsam of Peru of Salvador is procured within the department of Sonsonate. The British Consul thus describes its production:—

In the district of Cuisnagua there are 3574 trees, which yield altogether only 600 lbs. of the gum annually. With proper care in the extraction, each tree would yield 2 lbs. to 3 lbs., making the total quantity capable of being produced in the before-mentioned district about 10,000 lbs. When the season has been more rainy than usual, the product is much lower; but in order to meet this difficulty, the Indians heat the body of the tree by fire, by this means causing the gum to exude more freely, but this operation invariably causes the decay of the tree.

The Indians employed in collecting the gum say that such trees as are well shaded yield a greater quantity; but that those which have been planted by hand yield the most. This has been proved by experience, particularly in Calcutta, where a considerable quantity is yearly collected from trees which have been so planted. During the months of December and January the gum oozes away spontaneously. This class of gum is called "calcawzate." It is orange-coloured, weighs less than the other, and emits a strong odour; is volatile and pungent.

BALSAM STORAX. See Storax.

BALSAM OF TOLU. (*Baume de Tolu*, Fr.; *Tolutanischer Balsam*, Germ.) *Balsam of Tolu* flows from the trunk of the *Myrospermum Toluiferum*, a tree which grows in South America, on the mountains of Tolu, Timbaceo, &c. It is, when fresh, of the consistence of turpentine; is brownish-red, dries into a yellowish or reddish brittle resinous mass, of a smell like benzoin; is soluble in alcohol and ether; affords, with water, benzoic acid. It appears probable that both the balsams of Peru and of Tolu are obtained from one tree. *Balsam of Tolu* is used to manufacture Tolu lozenges, and the Syrup of Tolu for irritating coughs. It is sometimes employed by confectioners to flavour sweetmeats, by perfumers, and in the formation of *fumigating pastiles.*

BAMBOO. (*Bambou*, Fr.; *Indianisches Rohr*, Germ.) A species of cane, the

Digitized by Google

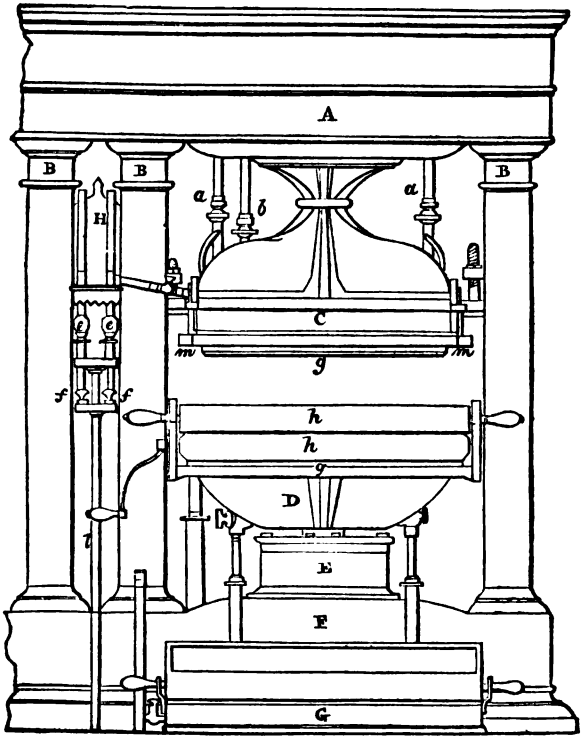
Bambos arundinacea of botanists. A most important vegetable product in the East, where it is used in the construction of houses, boats, bridges, &c. Its grain is used for bread; its fibre is manufactured into paper. Walking sticks are said to be of bamboo; they are the *ratan*, a different plant.

BANANA. An herbaceous endogenous plant *Musa sapientum*, growing in the West Indies. The Plaintain has a fruit which is used for food to an immense extent by the inhabitants of hot climates, forming, indeed, a necessary article of diet. See MUSACEÆ.

BANDANNA. A style of calico printing, in which white or brightly-coloured spots are produced upon a red or dark ground. It seems to have been practised from time immemorial in India, by binding up firmly with thread those points of the cloth which were to remain white or yellow, while the rest of the surface was freely subjected to the dyeing operations.

The European imitations have now far surpassed, in the beauty and precision of the design, the oriental patterns, having called into action the refined resources of mechanical and chemical science. The white spots are produced by a solution of chlorine, made to percolate down through the Turkey red cotton cloth, in certain points defined and circumscribed by the pressure of hollow lead types in plates, in a hydraulic press. *Fig.* 155 is an elevation of one press: A, the top of the entablature; B B, the cheeks

157



or pillars; C, the upper block for fastening the upper lead perforated pattern to; D, the lower block to which the fellow pattern is affixed, and which moves up and down with the piston of the press; E, the piston or ram; F, the sole or base; G, the water-trough for the discharged or spotted calico to fall into; H, the small cistern for the aqueous chlorine or liquor-metre, with glass tubes for indicating the height of liquor inside the cistern; *e e*, glass stopcocks, for admitting the liquor into that cistern from the general reservoir; *f f*, stopcocks for admitting water to wash out the chlorine; *g g*, the pattern lead-plates, with screws for setting the patterns parallel to each other;

Digitized by Google

m m, projecting angular pieces at each corner, perforated with a half-inch hole to receive the four guide-pins rising from the lower plate, which serve to secure accuracy of adjustment between the two faces of the lead pattern plates; *h h*, two rollers, which seize and pull through the discharged pieces, and deliver them into the water trough. To the left of D there is a stopcock for filling the trough with water; *l* is the waste tub for chlorine liquor and water of washing. The contrivance for blowing a stream of air across the cloth through the pattern holes is not represented in the figure.

Sixteen engines, similar to the above, each possessing the power of pressing with several hundred tons, are arranged in one line, in subdivisions of four, the spaces between each subdivision serving as passages to allow the workmen to go readily from the front to the back of the presses. Each occupies 25 feet, so that the total length of the apartment is 100 feet.

To each press is attached a pair of patterns in lead (or plates as they are called), the manner of forming which will be described in the sequel. One of these plates is fixed to the upper block of the press. This block is so contrived that it rests upon a kind of universal joint, which enables this plate to be applied exactly to the under fellow-plate. The latter sits on the movable part of the press, commonly called the sill. When this is forced up, the two patterns close on each other very nicely by means of the guide-pins at the corners, which are fitted with the utmost care.

The power which impels this great hydrostatic range is placed in a separate apartment, called the machinery room. This machinery consists of two press cylinders of a peculiar construction, having solid rams accurately fitted to them. To each of these cylinders three little force-pumps, worked by a steam-engine, are connected.

The piston of a large cylinder is eight inches in diameter, and is loaded with a top weight of five tons. This piston can be made to rise about two feet through a leather stuffing or collar. The other cylinder has a piston of only one inch in diameter, which is also loaded with a top weight of five tons. It is capable, like the other, of being raised two feet through its collar.

Supposing the pistons to be at their lowest point, four of the six small force-pumps are put in action by the steam-engine, two of them to raise the large piston, and two the little one. In a short time so much water is injected into the cylinders that the loaded pistons have arrived at their highest points. They are now ready for working the hydrostatic discharge presses, the water pressure being conveyed from the one apartment to the other, under ground, through strong copper tubes of small calibre.

Two valves are attached to each press, one opening a communication between the large driving cylinder and the cylinder of the press, the other between the small driving cylinder and the press. The function of the first is simply to lift the under block of the press into contact with the upper block; that of the second is to give the requisite compression to the cloth. A third valve is attached to the press for the purpose of discharging the water from its cylinder, when the press is to be relaxed in order to remove or draw through the cloth.

From 12 to 14 pieces of cloth previously dyed Turkey red, are stretched over each other as parallel as possible, by a particular machine. These parallel layers are then rolled round a wooden cylinder, called by the workmen a drum. This cylinder is now placed in its proper situation at the back of the press. A portion of the 14 layers of cloth, equal to the area of the plates, is next drawn through between them by hooks attached to the two corners of the webs. On opening the valve connected with the eight-inch driving cylinder, the water enters the cylinder of the press, and instantly lifts its lower block so as to apply the under plate with its cloth close to the upper one. This valve is then shut and the other is opened. The pressure of five tons in the one-inch prime cylinder is now brought to bear on the piston of the press, which is eight inches in diameter. The effective force here will therefore be $5 \text{ tons} \times 8^2 = 320$ tons, the areas of cylinders being to each other as the squares of their respective diameters. The cloth is thus condensed between the leaden pattern plates with a pressure of 320 tons in a couple of seconds.

The next step is to admit the bleaching or discharging liquor (aqueous chlorine, obtained by adding sulphuric acid to solution of chloride of lime) to the cloth. This liquor is contained in a large cistern in an adjoining house, from which it is run at pleasure into small lead cisterns, H, attached to the presses, which cisterns have graduated index tubes for regulating the quantity of liquor according to the pattern of discharge. The stopcocks on the pipes and cisterns containing this liquor are all made of glass.

From the measure-cistern, H, the liquor is allowed to flow into the hollows in the upper lead plate, whence it descends on the cloth, and percolates through it, extracting in its passage the Turkey-red dye. The liquor is finally conveyed into the waste pipe from a groove in the under block. As soon as the chlorine liquor has passed through, water is admitted in a similar manner to wash away the chlorine, otherwise,

Digitized by Google

upon relaxing the pressure, the outline of the figure discharged would become ragged. The passage of the discharge liquor, as well as of the water through the cloth, is occasionally aided by a pneumatic apparatus, or blowing machine, consisting of a large gasometer from which the air, subjected to a moderate pressure, may be allowed to issue and act, in the direction of the liquid, upon the folds of the cloth. By an occasional twist of the air stopcock, the workman also can ensure the equal distribution of the discharging liquor over the whole excavations in the upper plate. When the demand for goods is very brisk, the air apparatus is much employed, as it enables the workman to double his product.

The time requisite for completing the discharging process in the first press is sufficient to enable the other three workmen to put the remaining 15 presses in play. The discharger proceeds now from press to press, admits the liquor, the air, and the water; and is followed at a proper interval by the assistants, who relax the press, move forwards another square of the cloth, and then restore the pressure. Whenever the sixteenth press has been liquored, &c., it is time to open the first press. In this routine about ten minutes are employed; that is, 224 handkerchiefs (16 × 14) are discharged every ten minutes. The whole cloth is drawn successively forward, to be successively treated according to the above method.

When the cloth is removed from the press it is passed between the two rollers in front, from which it falls into a trough of water placed below. It is finally carried off to the washing and bleaching department, where the lustre of both the white and the red is considerably brightened.

By the above arrangement of presses, 1600 pieces, consisting of 12 yards each = 19,200 yards, are converted into bandannas in the space of ten hours, by the labour of four workmen.

The patterns, or plates, which are put into the presses to determine the white figures on the cloth, are made of lead in the following way:—A trellis frame of cast iron, one inch thick, with turned-up edges, forming a trough rather larger than the intended lead pattern, is used as the solid groundwork. Into this trough a lead plate, about one half-inch thick, is firmly fixed by screw-nails passing up from below. To the edges of this lead plate the borders of the piece of sheet lead are soldered, which covers the whole outer surface of the iron frame. Thus a strong trough is formed, one inch deep. The upright border gives at once great strength to the plate and serves to confine the liquor. A thin sheet of lead is now laid on the thick lead plate, in the manner of a veneer on toilette tables, and is soldered to it round the edges. Both sheets must be made very smooth beforehand, by hammering them on a smooth stone table, and then finishing with a plane; the surface of the thin sheet (now attached) is to be covered with drawing paper, pasted on, and upon this the pattern is drawn. It is now ready for the cutter. The first thing which he does is to fix down with brass pins all the parts of the pattern which are to be left solid. He now proceeds with the little tools generally used by block-cutters, which are fitted to the different curvatures of the pattern, and he cuts perpendicularly quite through the thin sheet. The pieces thus detached are easily lifted out, and thus the channels are formed which design the white figures on the red cloth. At the bottom of the channels a sufficient number of small perforations are made through the thicker sheet lead, so that the discharging liquor may have free ingress and egress. Thus one plate is finished, from which an impression is taken in the hydrostatic press, by means of printers' ink, on paper pasted upon another plate. Each pair of plates constitutes a set which may be put into presses and removed at pleasure.

BANDOLINE, called also *clysphitique* and *fixature*, a mucilage of Carrageen moss; used for stiffening the hair and keeping it in order.

BARBARY GUM. Sometimes called *Morocco gum*. The product of the *Acacia gummifera*. Imported from Tripoli, Barbary, and Morocco. See ARABIC, GUM.

BARBERRY. (*Berberris*, Lat.; *Épine-vinette*, Fr.) It is probable that this name has been given to this plant from its spines, or *barbs*. The name *Oxycanthus*, also given to it, indicates a like origin.

The barberry is a shrubby plant, common in hedges in England; sometimes called the pipperidge bush. The berries are used in housewifery. The root of this plant contains a yellow colouring matter which is soluble in water and alcohol, and is rendered brown by alkalis. The solution is employed in the manufacture of morocco leather.

BARILLA. (*Soude*, *Barille*, Fr.; *Barilla*, Germ.) A crude soda, procured by the incineration of the *salsola soda*, a plant cultivated for this purpose in Spain, Sicily, Sardinia, and the Canary Islands. In Alicante the plants are raised from seed, which is sown at the close of the year, and they are usually fit to be gathered in September following. In October the plants are usually burned. For this purpose holes are made in the earth, capable of containing a ton or a ton and a half of soda. Iron bars

Digitized by Google

are laid across these cavities, and the dried plants, stratified with dry seeds, are placed upon them. The whole is set on fire. The alkali contained in the plants is fused, and it flows into the cavity beneath, a red-hot fluid. By constantly heaping on plants, the burning is continued until the pits are full of barilla; they are then covered up with earth and allowed to cool gradually. The spongy mass of alkali, when sufficiently cold, is broken out, and, without any further preparation, it is ready for shipment. Good barilla usually contains, according to Dr. Ure's analysis. 20 per cent. of real alkali associated with muriates and sulphates, chiefly of soda, some lime, and alumina, with very little sulphur. Caustic leys made from it were formerly used in the finishing process of the hard soap manufacture.

The manufacture of barilla has greatly declined since the introduction of Le Blanc's process for artificially manufacturing soda from common salt. In 1856 we *imported* 54,608 cwts., and in 1864 the following quantities of barilla were *imported*:—

	Cwt.	Computed real value.
From Canary Islands - - -	16,450	£4,524

„ Other parts - - - -	1,065	693
	25,251	10,245

BARIUM. (From *βάρυς, heavy.*) The metallic basis of the earth baryta was obtained by Davy, in 1808, by the voltaic decomposition of the moistened carbonate of baryta in contact with mercury. It may likewise be procured by passing potassium in vapour over baryta heated to redness in an iron tube, and afterwards withdrawing the reduced barium which the residuum contains, by means of mercury. The latter metal is separated by distillation in a glass retort, care being taken not to raise the temperature to redness, for the barium then decomposes glass.

Barium is a white metal, like silver, fusible under a red heat, denser than oil of vitriol, in which it sinks.—*Graham.*

BARIUM, OXIDES OF. There are two oxides of barium, a protoxide Ba^2O (barytes) and a peroxide BaO or BaO^2. See BARYTA.

BARIUM, SALTS OF:—

BROMIDE OF BARIUM. Prepared by saturating baryta water with hydrobromic acid.

CHLORIDE OF BARIUM. Made from the native sulphate (heavy spar), by igniting in a crucible with pounded coal. The commercial chloride frequently contains small quantities of the chlorides of strontian and calcium. Chloride of barium is especially used for the detection and estimation of sulphuric acid.

BARIUM, FLUORIDE OF. Prepared by neutralising baryta water by hydrofluoric acid.

BARIUM IODIDE is formed when hydriodic acid is passed over baryta at a red heat.

BARK. The outer rind of plants. Many varieties of barks are known to commerce, but the term is especially used to express either Peruvian or Jesuits' bark, a pharmaceutical remedy, or Oak bark, which is very extensively used by tanners and dyers.

The varieties known in commerce are:—

CORK BARK. (Fr. *Liége*; *Kork*, Germ.); which see.
OAK BARK. (*Tan brut*, Fr.; *Eichenrinde*, Germ.); which see.
PERUVIAN BARK. (*Quinquina*, Fr.; *Chinarinde*, Germ.); which see.
QUERCITRON BARK: which see.
WATTLE BARK: which see.

The following were our *Importations* for 1864 of barks for tanners' or dyers' use, varieties unenumerated:—

	Cwt.	Computed real value.
From Holland - - - -	49,802	£16,277
„ Belgium - - - -	133,626	44,756
„ Italy: Sardinian States -	18,411	7,596
„ Sicily - - - - -	7,945	3,277
„ Australia - - - -	39,966	22,528
„ Other Parts - - - -	19,374	6,530
	269,124	100,964

Of these barks we *exported* for tanners' use, 977 cwt.

BARK BREAD. A kind of bread prepared in many parts of Norway by the poorer peasants from the inner bark of the *Pinus Sylvestris*. See PINUS.

BARLEY. (*Orge*, Fr.; *Gerstengraupe*, Germ.;) *Hordeum*, Linn. This term is supposed to be derived from *hordus*, heavy, because the bread made from it is very

Digitized by Google

heavy. Barley belongs to the class *Endogens*, or *Monocotyledons*; *Glumel Alliance*, of Linley: natural order, *Graminaceæ*.

There are four species of barley cultivated in this country:—

1. *Hordeum hexastichon.* Six-rowed barley, or Winter-barley.
2. *Hordeum vulgare.* The Scotch bere or bigg; the four-rowed barley.
3. *Hordeum zeocriton.* Putney, fan, sprat, or battledore barley.
4. *Hordeum distichum.* Two-rowed long-eared barley, or Summer barley.

Barley and oats are the cereals whose cultivation extends farthest north in Europe.

The specific gravity of English barley varies from 1·25 to 1·33; of bigg from 1·227 to 1·265; the weight of the husk of barley is $\frac{1}{5}$, that of bigg $\frac{2}{5}$. Specific gravity of barley is 1·235, by Dr. Ure's trials. 1000 parts of barley flour contain, according to Einhof, 720 of starch, 56 sugar, 50 mucilage, 36·6 gluten, 12·3 vegetable albumen, 100 water, 2·5 phosphate of lime, 68 fibrous or ligneous matter.

From the examination instituted by the Royal Agricultural Society of England, and carried out under the directions of Messrs. Way and Ogston, the following results have been arrived at:—

Kind of Barley employed.	Moisture in 100 Parts of Grain.	Specific Gravity of Grains.	Ash in 100 Parts of dried Grain.
Unknown	12·00		2·43
Chevalier barley	10·00	1·260	2·50
Ditto	16·00	1·234	2·82
Ditto, from Moldavia	11·00	1·268	2·38
Ditto	16·00		2·75
Grains of Chevalier barley	15·00		14·23

The analyses of several varieties gave as the composition of the ashes of the grains of barley:—

	Unknown.	Chevalier Barley.	From Moldavia.	Chevalier Barley.
Potash	21·14	20·77	37·55	7·70
Soda		4·56	1·06	0·36
Lime	1·65	1·48	1·21	10·36
Magnesia	7·26	7·45	10·17	1·26
Sesquioxide of iron	2·13	0·51	1·02	1·46
Sulphuric acid	1·91	0·79	0·27	2·99
Silica	30·68	32·73	24·56	70·77
Phosphoric acid	28·53	31·89	28·64	1·99
Chloride of sodium	1·01		1·47	1·10

In the "Synopsis of the Vegetable Products of Scotland," by Peter Lawson and Son, will be found the best description of all the different varieties of barley; and, since the Lawsonian collection is in the museum of the Royal Botanic Gardens at Kew, the grains can be examined readily by all who take any interest in the subject. A few only of the varieties will be noticed.

The true six-rowed Barley, known also as Pomeranian and as six-rowed white winter barley.—This is a coarse barley, but hardy and prolific. It is occasionally sown in France, and also in this country, sometimes as a winter and sometimes as a spring barley, and is found to answer pretty well as either.

Naked two-rowed.—Ear long, containing twenty-eight or thirty very large grains, which separate from the palea, or chaff, in the manner of wheat. This variety has been introduced to the notice of agriculturalists at various times, and under different names, but its cultivation has never been carried to any great extent.

Common Bere, Bigg, or rough Barley.—This variety is chiefly cultivated in the Highlands of Scotland, and in the Lowlands on exposed inferior soils.

Victoria.—A superior variety of the old bigg, compared with which it produces longer straw, and is long-eared, often containing 70 or 100 grains in each. Instances have been known of its yielding 13 quarters per acre, and weighing as much as 96 lbs per bushel.

Beyond these there are, *the winter black; the winter white; old Scottish four-rowed; naked, golden*, or *Italian*; *Suffolk* or *Norfolk*, and *Short-necked*; cultivated in various districts, and with varying qualities. See BEER.

BARLEY, PEARL and POT. When barley is deprived of its husk by a mill, it forms the *Scotch*, *Hulled*, or *Pot Barley*. When all the integuments of the grains are removed, and the seeds are rounded and polished, they constitute *Pearl Barley*. The flour obtained by grinding pearl barley to powder is called *Patent Barley*.

Of English pearl barley in 1864 we exported 12,811 cwts.

BARLEY SUGAR. Sugar boiled until it is quite transparent and crisp: formerly in barley water. It is flavoured with either orange or lemon peel.

BARM. (Derived from the Saxon *beorme*; or from *beer-rahm*, beer-cream.) The yeasty top of fermenting beer. It is used as leaven in bread, and to establish fermentation in liquors. See BEER, FERMENTATION.

BARRÉGE. A woollen fabric, in both warp and woof, which takes its name from the district in which it was first manufactured—the especial locality being a little village named Arosons, in the beautiful valley of Barrèges. It was first employed as an ornament for the head, especially for sacred ceremonies, as baptism and marriage. Paris subsequently became celebrated for its barrèges, but these were generally woven with a warp of silk. Enormous quantities of cheap barrèges are now made with a warp of cotton.

BARREL. (*Baril*, Fr.) A round vessel, or cask, of greater length than breadth, made of staves, and hooped.

The English barrel—wine measure contains 31½ gallons.

„	(old) beer	„	36	„
„	(old) ale	„	32	„
„	beer vinegar	„	34	„
„	contains 126 Paris pints.			

The ale and beer barrels were equalised to 34 gallons by a statute of William and Mary. The wine gallon, by a statute of Anne, was declared to be 231 cubic inches; the beer gallon being usually reckoned as 282 cubic inches. The imperial gallon is 277·274 cubic inches. The old barrels now in use are as follows:—

Wine barrel - - - - -		$26\frac{1}{4}$	imperial gallons.
Ale „ (London) - - -		$33\frac{39}{59}$	„
Beer „ - - - - -		$36\frac{19}{59}$	„
Ale and beer, for England - -		$34\frac{34}{59}$	„

The *baril de Florence* is equivalent to 20 bottles.

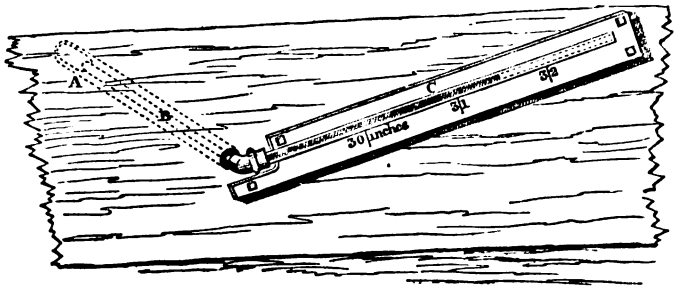
The Connecticut barrel for liquors is 31½ gallons, each gallon to contain 231 cubic inches. The statute barrel of America must be from 28 to 31 gallons. The barrel of flour, New York, must contain either 195 lbs. or 228 lbs. nett weight. The barrel of beef or pork in New York and Connecticut is 200 lbs. A barrel of Essex butter is 106 lbs. A barrel of Suffolk butter is 256 lbs. A barrel of herrings should hold 1000 fish. A barrel of salmon should measure 42 gallons.

BAROMETER. This name signifies a *measurer of weight*—the column of mercury in the tube of the barometer being exactly balanced against the weight of a column of air of the same diameter, reaching from the surface of the earth to the extreme limits of the atmosphere. The length of this column of mercury is never more than thirty-one inches; below that point it may vary, according to conditions, through several inches. There have been many useful applications of the barometer, but the only one with which this dictionary has to deal appears to be the following:—

Digitized by Google

Barometer, Mackworth's Underground. — In the goafs, or old workings, of some mines hollows exist, in which explosive or noxious gases tend to accumulate in considerable quantity. When the barometer falls, these gases expand and approach or enter the working places of the mine, producing disastrous results to life or health. To enable the manager of a mine to foresee these contingencies, he has but to construct a small model of such a cavity, and let the expansion or contraction of the gas measure itself. In *fig.* 156 A, is a brass vessel, 12 inches long and 1¼ inches in diameter,

156



closed at each end. In one end is inserted a copper tube, ¼th inch in diameter and 12 feet long, B. A hole, 2 inches in diameter, being bored 12 feet deep into the solid coal or rock, the brass vessel is pushed to the bottom of it, and the small tube is closely packed round with coal or clay. C is a glass tube, 4 feet long and ¼th inch in diameter, in which is placed water or oil. As the external atmosphere presses, the surface of the liquid rises or falls, and the scale is graduated by comparison with a standard barometer. The air contained in the brass vessel A, and copper tube B, is unaffected, or nearly so, by temperature, and no correction has to be made for the latter as in the sympiesometer. A and B may be conveniently filled with nitrogen, to prevent the oxidation of the metal; and the surface of the liquid in the glass tube may be made self-registering, either giving maxima and minima, or, by the addition of clockwork, taking diagrams on paper.

BARWOOD. Although distinctions are made between sandal or saunders wood, camwood, and barwood, they appear to be very nearly allied to each other — at least, the colouring matter is of the same composition. They come, however, from different places. See CAMWOOD and SANDAL WOOD.

MM. Girardin and Preisser thus describe this wood: —

This wood, in the state of a coarse powder, is of a bright red colour, without any odour or smell. It imparts scarcely any colour to the saliva.

Cold water, in contact with this powder, only acquires a fawn tint after five days' maceration. 100 parts of water only dissolve 2·21 of substances consisting of 0·85 colouring matter and of 1·36 saline compounds. Boiling water becomes more strongly coloured of a reddish yellow; but, on cooling, it deposits a part of the colouring principle in the form of a red powder. 100 parts of water at 212° dissolve 8·86 of substances consisting of 7·24 colouring principle, and 1·62 salts, especially sulphates and chlorides. On macerating the powder in strong alcohol, the liquid almost immediately acquires a very dark vinous red colour. To remove the whole of the colour from fifteen grains of this powder, it was necessary to treat it several times with boiling alcohol. The alcoholic liquid contained 0·23 of colouring principle and 0·004 of salt. Barwood contains, therefore, 23 per cent of red colouring matter; whilst saunders wood, according to Pelletier, only contains 16·75.

The alcoholic solution behaves in the following manner towards re-agents: —

Distilled water added in great quantity -	Produces a considerable yellow opalescence. The precipitate is re dissolved by the fixed alkalis, and the liquor acquires a dark vinous colour.
Fixed alkalis - - - - -	Turn it dark crimson, or dark violet.
Lime water - - - - -	Ditto.
Sulphuric acid - - - - -	Darkens the colour to a cochineal red.
Sulphuretted hydrogen - - -	Acts like water.
Salt of tin - - - - -	Blood-red precipitate.
Chloride of tin - - - - -	Brick-red precipitate.

Digitized by Google

Acetate of lead	Dark violet gelatinous precipitate.
Salts of the protoxide of iron	Very abundant violet precipitates.
Copper salts	Violet-brown gelatinous precipitates.
Chloride of mercury	An abundant precipitate of a brick-red colour.
Nitrate of bismuth	Gives a light and brilliant crimson red.
Sulphate of zinc	Bright red flocculent precipitate.
Tartar emetic	An abundant precipitate of a dark cherry colour.
Neutral salts of potash	Act like pure water.
Water of barytes	Dark violet-brown precipitate.
Gelatine	Brownish-yellow ochrous precipitate.
Chlorine	Brings back the liquor to a light yellow, with a slight yellowish-brown precipitate, resembling hydrated peroxide of iron.

Pyroxylic spirit acts on barwood like alcohol, and the strongly coloured solution behaves similarly towards re-agents. Hydrated ether almost immediately acquires an orange-red tint, rather paler than that with alcohol. It dissoves 19·47 per cent. colouring principle. Ammonia, potash, and soda, in contact with powdered barwood, assume an extremely dark violet-red colour. These solutions, neutralised with hydrochloric acid, deposit the colouring matter in the form of a dark reddish-brown powder. Acetic acid becomes of a dark-red colour, as with saunders wood.

Barwood is but slightly soluble; but the difficulty arising from its slight solubility is, according to Mr. Napier, overcome by the following very ingenious arrangement: —The colouring matter while hot combines easily with the proto-compounds of tin, forming an insoluble rich red colour. The goods to be dyed are impregnated with proto-chloride of tin combined with sumach. The proper proportion of barwood for the colour wanted is put into a boiler with water, and brought to boil. The goods thus impregnated are put into this boiling water containing the rasped wood, and the small portion of colouring matter dissolved in the water is immediately taken up by the goods. The water, thus exhausted, dissolves a new portion of colouring matter, which is again taken up by the goods, and so on till the tin upon the cloth has become (if we may so term it) saturated. The colour is then at its brightest and richest phase.

Our importations of bar wood have been :—

BARYTA, or BARYTES. (*Baryte*, Fr.) One of the simple earths. It may be obtained most easily by dissolving the native carbonate of barytes (*Witherite*, after Withering, who described it, "Phil. Transactions," 1784) in nitric acid, evaporating the neutral nitrate till crystals be formed, draining and then calcining these, by successive portions, in a covered platina crucible, at a bright red heat. A less pure baryta may be obtained by igniting strongly a mixture of the carbonate and charcoal, both in fine powder and moistened. It is a greyish-white earthy-looking substance, fusible only at the jet of the oxy-hydrogen blowpipe, has a sharp caustic taste, corrodes the tongue and all animal matter, is poisonous even in small quantities, has a very powerful alkaline reaction; a specific gravity of 4·0; becomes hot, and slakes violently when sprinkled with water, falling into a fine white powder, called the hydrate of baryta, which contains 10½ per cent. of water, and dissolves in 10 parts of boiling water. This solution lets fall abundant columnar crystals of hydrate of baryta as it cools; but it still retains one-twentieth its weight of baryta, and is called baryta water. The above crystals contain 61 per cent. of water, of which, by drying, they lose 50 parts. This hydrate may be fused at a red heat without losing any more water. Of all the bases, baryta has the strongest affinity for sulphuric acid, and is hence employed—either in the state of the above water, or in that of one of its neutral salts, as the nitrate of muriate—to detect the presence and determine the quantity of that acid present in any soluble compound. Its prime equivalent is 7·66, hydrogen being 1000.

BARYTA, CARBONATE OF. The composition of the native carbonate of barya may be regarded as baryta 77·59 and carbonic acid 22·41. It is found in Shropshire, Cumberland, Westmoreland, and Northumberland. The carbonate of baryta is employed in our colour manufactories as a base for some of the more delicate colours; it is also used in the manufacture of plate-glass; and, in France, it is much used in the preparation of beet-root sugar.

A small quantity only of carbonate of baryta is now produced in this country; in 1864 a few tons were sold from Alston Moor, and a little from Snailbeach, in Shropshire.

Digitized by Google

BARYTA, SULPHATE OF. The baryte of Brooke and Miller, barytes of Dana and Phillips, Bolognian spar, called also "cawk" and "heavy spar." It is composed of baryta 65·63, sulphuric acid 34·37, with sometimes a little iron, lime, or silica.

This salt of baryta is very extensively spread over various parts of the islands. It might be obtained in very large quantities in Devonshire, Cornwall, and other places, if the demand for it sufficiently increased the price so as to render the working of it profitable. It is worked in Derbyshire, Yorkshire, Shropshire, and the Isle of Arran. The white varieties are ground after being heated and thrown into water, and the heavy white powder is employed in adulterating white lead. On this account it is very difficult to obtain correct returns. The probable production of 1864 was :—

	Tons.
Derbyshire, about	4500
Shropshire „	1250
Bantry (Ireland)	500
Isle of Arran	650
Kirkcudbright	100

We exported of Barytes as follows :—

BARYTA NITRATE. This salt is used in pyrotechny for making *green fire*. The best mixture is nitrate of baryta 77 parts, sulphur 13 parts, chlorate of potash 5 parts, metallic arsenic 2 parts, charcoal 3 parts.

BASALT. One of the most common varieties of trap rock. It is a dark green or black stone, composed of augite and felspar, very compact in texture, and of considerable hardness, often found in regular pillars of three or more sides, called "basaltic columns." Remarkable examples of this kind are seen at the Giant's Causeway in Ireland, and at Fingal's Cave, in Staffa, one of the Hebrides. Messrs. Chance (brothers) of Birmingham, have adopted the process of melting the Rowley rag, a basaltic rock forming the plateau of the Rowley hills, near Dudley, South Staffordshire, and then casting it into moulds for architectural ornaments, tiles for pavements &c. Not only the Rowley rag, but basalt, greenstone, whinstone, or any similar mineral, may be used. The material is melted in a reverberatory furnace, and when in a sufficiently fluid state, is poured into moulds of sand encased in iron boxes, these moulds having been previously raised to a red heat in ovens suitable for the purpose. The object to be attained by heating the moulds previous to their reception of the liquid material is to retard the rate of cooling; as the result of slow cooling is a hard, strong, and stony substance, closely resembling the natural stone, while the result of rapid cooling is a dark brittle glass.

BASILICON. The name given by the old apothecaries to a mixture of oil, wax, and resin, which is represented by the *Cerat resinæ* of the present day.

BASKETS. Weaving of rods into baskets is one of the most ancient of the arts amongst men; and it is practised in almost every part of the globe, whether inhabited by civilised or savage races. Basket-making requires no description here.

We imported in 1864 Baskets of the computed real value given :—

From Hamburg	£6,395
France	31,671
Portugal	2,960
Other Parts	1,860
	42,886

BASSORA GUM. A gum obtained from the *Acacia leucophlæa*, brought from Bassora. It has a specific gravity of 1·3591, and is yellowish white in colour.

BASSORINE. A constituent part of gum Bassora, as also of gum tragacanth. It is semi-transparent, difficult to pulverise, swells considerably in cold or boiling water, and forms a thick mucilage without dissolving.

BASS or BAST. The Russian mats used by gardeners and upholsterers, made from the bark of the Lime or Linden tree, are called Bast mats. The name is also used for the bark or tough fibres of the flax and hemp plants of which Bast brooms are made. The thick mat or hassock used by persons to kneel on at church is called a Bass.

We imported of Bast or Bast Ropes as follows :—

BATH METAL consists of 3 oz. of zinc to 1 lb. of copper. — See BRASS.

BATHS. (*Bains*, Fr.; *Baden*, Germ.) The importance attached by the Greeks and Romans to bathing is sufficiently attested by the remains of magnificent structures which still excite the admiration of the beholder, and by the beautiful specimens of fresco-painting and sculpture discovered in their baths.

It is computed that in the baths of Caracalla, as many as three thousand people could bathe at the same time, in water at various degrees of temperature, to suit their inclinations. The warm and hot baths were, however, almost exclusively in use under the Emperors.

During the Republic the baths were cold. Mecænas was the first to erect warm and hot ones for public use; they were called Thermæ, and were placed under the direction of ediles, who regulated the temperature, enforced cleanliness in the establishment, and order and decorum among the visitors. Agrippa, during the time he was edile, increased the number of thermæ to 170, and in the course of two centuries, there were no less than eight hundred in imperial Rome. The inhabitants resorted to the baths at particular hours, indicated by striking a bell or gong. Adrian forbade their being open before eight in the morning, except in cases of sickness; whereas Alexander Severus not only permitted them to be open during the whole day, but also to be used through the night in the great heats of summer.

It was a common practice with the Romans to bathe towards evening, and particularly before supper: some of the more luxurious made use of the bath even after this meal. We are told of many citizens of distinction who were in the habit of bathing four, or five, and even eight times a day. Bathing constituted a part of public rejoicings, equally with the other spectacles, and, like them, was prohibited when the country suffered under any calamity. All classes resorted to the baths; the emperors themselves, such as Titus, Adrian, and Alexander Severus, were occasionally seen among the bathers. The price of admission was very small, amounting to no more than a farthing. — *E. Lee, on Mineral Waters and Baths.*

Warm baths have come into very general use in England, and they are now considered as indispensably necessary in all modern houses of any magnitude, as also in club-houses, hotels, and hospitals; and the mode of constructing baths, and of obtaining the necessary supplies of hot and cold water, has undergone much improvement with the extension of their employment.

The several points in regard to warm baths are,

1. The materials of which they are constructed.
2. Their situation.
3. The supply of cold water.
4. The supply of hot water.
5. Minor comforts and conveniences.

1. As to the materials of which they are constructed. — Of these the best are slabs of polished marble, properly bedded with good water-tight cement, in a seasoned wooden case, and neatly and carefully united at their respective edges. These, when originally well constructed, form a durable, pleasant, and agreeable-looking bath, but the expense is often objectionable, and, in upper chambers, the weight may prove inconvenient. If of white or veined marble, they are also apt to get yellow or discoloured by frequent use, and cannot easily be cleansed; so that large Dutch tiles, as they are called, or square pieces of white earthenware, are sometimes substituted. Welsh slate has now superseded marble to a great extent; and very superior baths are now manufactured of Stourbridge clay, at Stourbridge. Copper, tinned or galvanised iron, are also employed; the first is most expensive in the outfit, but far more durable than the latter.

2. As to the situation of the bath, or the part of the house in which it is to be placed.—In hotels and club-houses, this is a question easily determined; several baths are usually here required, and each should have annexed to it a properly warmed dressing-room. Whether they are upstairs or downstairs is a question of convenience, but the basement story, in which they are sometimes placed, should always be avoided: there is a coldness and dampness belonging to it, in almost all weathers, which is neither agreeable nor salubrious.

In hospitals, there are usually several baths on each side of the house (the men's and women's), and the supply of hot water is ready at a moment's notice.

In private houses, the fittest places for warm baths are dressing-rooms annexed to the principal bed-rooms; or, where such convenience cannot be obtained, a separate bath-room connected with the dressing-room, and always upon the bed-room floor.

3. The supply of water is a very important point, as connected with the present subject. The water should be soft, clean, and pure; and as free as possible from all substances mechanically suspended in it.

Digitized by Google

4, and 5.—In public bathing establishments, where numerous and constant baths are required, the most effective means of obtaining hot water for their supply are now employed. It is drawn directly into the baths from a large boiler, placed somewhere above their level. The hot water enters the bath by a pipe at least an inch and a half in diameter, and the cold water by one of the same dimension. The relative proportions of the hot and cold water are, of course, to be adjusted by a thermometer; and every bath has a two-inch waste pipe, opening about two inches from the top of the bath, and suffering the excess of water freely to run off; so that when a person is immersed in the bath, or when the supplies of water are accidently left open, there may be no danger of an overflow.

A contrivance of some ingenuity consists in suffering the water for the supply of the bath to flow from a cistern above it, through a leaden pipe of about one inch diameter, which is conducted into the kitchen or other convenient place, where a large boiler for the supply of hot water is already fixed. The bath-pipe is immersed in this boiler, in which it makes many convolutions, and, again emerging, ascends to the bath. The operation is simply this:—the cold water passing through the convolutions of that part of the pipe which is immersed in the boiling water, receives there sufficient heat for the purpose required, and ascending, in obedience to the law of fluid pressure, it is delivered in that state by the ascending pipe into the bath, which is also supplied with cold water and waste-pipes as usual. The pipe may be of lead, as far as the descending and ascending parts are concerned, but the portion forming the worm or convolutions immersed in the boiler, should be copper, in order that the water within it may receive heat without impediment.

The facilities which are now afforded for the construction of baths in private houses, and for the use of them at a very cheap rate in public establishments, render it quite unnecessary to retain the remarks made by Dr. Ure.

Public baths and wash-houses have now become common amongst us, and with them an increased cleanliness is apparent, and improved health throughout the population.

The steady increase of the revenue derived from the baths and wash-houses in London, from the commencement of the undertaking in 1846, shows the practical utility of these institutions, and their effect on the physical and social condition of the industrious classes; viz.:—

	£	s.	d.
The aggregate receipts of nine establishments, during 1853, amount to	18,213	5	8
1852. Eight establishments	15.629	5	8
1851. Six establishments	12,906	12	5
1850. Four establishments	9,823	10	6
1849. Three establishments	6,379	17	2
1848. Two establishments	2,896	5	1
1847. 1846. Ditto	3,222	1	5

A similar increase has continued to the present time, the receipts being now, 1865, above £25,000. Those conveniences—now, indeed, become absolute necessities—are extending in every part of the country.

Baths, as curative agents, are of various kinds. Turkish Baths, for Rheumatism and other complaints:—in which are adopted all the processes which have been so much extolled in the Oriental bath system, have been introduced with success during the last four years. Although much lauded by some, they have not been so satisfactory to others; and do not therefore appear to be extending. Vapour Baths are stimulant and sudorific; they may be either to be breathed, or not to be breathed. Dr. Pereira has given the following Table, as a comparative view of the heating powers of vapour and of water:—

Kind of bath.	Water.	Vapour.	
		Not breathed.	Breathed.
Tepid bath	85° to 92°	96° to 106°	90° to 100°
Warm bath	92 „ 98	106 „ 120	100 „ 110
Hot bath	98 „ 106	120 „ 160	110 „ 130

Local vapour baths are applied in affections of the joints, and the like.

Vapour douche is a jet of aqueous vapour directed on some part of the body.

Medicated vapour baths are prepared by impregnating vapour with the odours of medicinal plants.

Digitized by Google

Sulphur, chlorine, sulphurous acid, iodine and camphor, are occasionally employed in conjunction with aqueous vapour.

Warm, *tepid*, and *hot baths* are sufficiently described above.

BATH BRICK. A brick made of calcareous and siliceous earth used in cleaning knives and for polishing purposes. They are made very extensively at and near Bridgewater from a deposit found in the Estuary there; a similar deposit is also worked at Cumwick, at the entrance of the Parrot River, and at Highbridge. At Bridgewater the average make is about 3,000,000 scouring bricks annually, which sell at about 2*l*. per thousand.

BATH METAL. An alloy in nearly equal quantities of copper and zinc.

BATH STONE. A building stone raised in the vicinity of the city of Bath. See OOLITE.

BAUXITE. A mineral which was at one time regarded as an ore of iron. It is so called from the name of the locality in France where it is found. Its composition is

Silica	2·8
Oxide of Titanium	3·1
Sesquioxide of Iron	25·5
Alumina	57·4
Carbonate of Lime	0·4
Water	10·8

It is now used as the source from which to obtain aluminium in the greatest purity. See ALUMINIUM.

BATHVILLITE. Dr. C. Greville Williams, who has been largely employed in the distillation of bituminous minerals, and amongst others of the *Torbanite* from Torbane Hill, near Bathgate, in Scotland, has discovered a brown friable substance occasionally filling the hollows of the above mineral. This is inflammable, and has been named *Bathvillite* by its discoverer.

BATT. A name given to a highly bituminous shale, which is often found interstratified with the coal. It occurs in the South Staffordshire coal field, and has been well described by Jukes in his *Geology of the South Staffordshire Coal Fields*. In Lancashire this shale is called *Black Bass*, and in Flintshire, where they are distilling it in considerable quantities, it is known as *Black Slag*.

BAULK. A piece of timber—the whole trunk of a tree. The term is applied by London timber merchants to wood in lengths of from 20 to 25 feet and 10 inches square.

BAY SALT. The larger crystalline salt of commerce. See SALT.

BAY, THE SWEET. (*Laurus nobilis*.) Bay leaves have a bitter aromatic taste, and an aromatic odour, which leads to their use in cookery.

BAYS, OIL OF. This oil is imported in barrels from Trieste. It is obtained from the fresh and ripe berries of the bay tree by bruising them in a mortar, boiling them for three hours in water, and then pressing them. When cold, the expressed oil is found floating on the top of the decoction. Its principal use is in the preparation of veterinary embrocations.

BDELLIUM. Two gum resins pass in commerce by this name. One is the false myrrh (the *Bdellium* of Scripture), the produce of the *Amyris commiphora*. The other is the *African Bdellium*, obtained from *Heudolatia Africana*. Pelletier gives the composition of the African bdellium as — resin, 59·0; soluble gum, 9·2; bassorin, 30·6; volatile oil and loss, 1·2.

BEADS. (*Grain*, Fr.; *Bethe*, Germ.) Perforated balls of glass, porcelain, or gems, strung and worn for ornaments; or, amongst some of the uncivilised races, employed instead of money.

The use of beads is of the highest antiquity. They are found in the tombs of Thebes and in the ruined temples of Assyria. They are discovered buried with the mighty dead of Greece. The Roman lady had them placed with her in her grave; and even in the burial-places of the ancient Britons we find beads, and these, too, of a similar pattern to such as we have every reason to believe are as old as Moses. Indeed, the peculiar ornamented zigzag pattern of the most ancient beads has been always, and still is manufactured at Venice, and found over the entire continent of Africa.

Glass beads have long been made in very large quantities in the glass-houses of Murano, at Venice.

Glass tubes, previously ornamented by colour and reticulation, are drawn out in proper sizes, from 100 to 200 feet in length, and of all possible colours. Not less than 200 shades are manufactured at Venice. These tubes are cut into lengths of

Digitized by Google

about two feet, and then, with a knife, they are cut into fragments, having about the same length as their diameter. The edges of these beads are, of course, sharp; and they are subjected to a process for removing this. Sand and wood-ashes are stirred with the beads, so that the perforations may be filled by the sand; this prevents the pieces of glass from adhering in the subsequent process, which consists in putting them into a revolving cylinder and heating them. The finished beads are sifted, sorted in various sizes, and strung by women for the market.

In the Jurors' Report of the Great Exhibition of 1851 are the following remarks on this manufacture: —

"The old Venetian manufactures of glass and glass wares fully sustain their importance; and those of paper, jewellery, wax-lights, velvets, and laces, rather exceeded their ordinary production. The one article of beads employs upwards of 5000 people at the principal fabric on the island of Murano; and the annual value is at least £200,000. They are exported to London, Marseilles, Hamburg, and thence to Africa and Asia, and the great Eastern Archipelago."

The *perles à la lune* are a finer, and, consequently, more expensive bead, which are prepared by twisting a small rod of glass, softened by a blowpipe, about an iron wire.

The preparation and cutting of gems into beads belong especially to the lapidary. The production of beads of PASTE, and of artificial PEARLS, will be noticed under those heads respectively.

In India beads of rock crystal are often very beautifully cut.

We *imported*, in 1864:—

	lbs.	Computed real value. £

BEAM TREE. (*Pyrus Aria*). The wood is used for axle trees, naves of wheels, and the cogs of machinery.

BEAN. (Faba.) See LEGUMINOSÆ.

BEAN ORE. Brown iron ore occurring in ellipsoidal concretions, called also BOHNERZ.

BEARINGS. The parts of a machine upon which the moveable portions are supported. Upon the correct adaptation of the rubbing surfaces to each other depends the value of a machine. If, for example, there should be much friction between the axle of a railway carriage and its *bearings*, there would be a large amount of power lost in overcoming that friction. The mechanical force—motion retarded—would (according to the received views of the present day—somewhat too hastily adopted) be converted into *heat*.

It has, therefore, been the study of engineers to produce bearings which should offer great resistance to pressure, and from their smoothings produce as little friction as possible.

KINGSTON'S METAL—*which see*,—has been lately used in the large engines for our iron clad fleet. Some of the railway companies are using an alloy of equal parts of tin and copper. Gun metal is, however, commonly employed for the bearings of machines. See BRONZE; COPPER; UNGUENTS.

BEAVER, THE. (*Castor Fiber.*) This animal is captured for its skin, and for the castor (*castoreum*), which is employed medicinally. See FURS.

BEBIRINE, or BEBEERINE. ($C^{36}H^{21}NO^4$.) An alkali discovered by Dr. Rodie, of Demerara, in the bark of the bebeern tree. It was examined more minutely by Madagan and Tilley, and still more recently by Von Planta, who has determined its true formula. It is very bitter, and highly febrifuge.

BEECH. (*Hêtre commun*, Fr.; *Gemeine Buche*, Germ.) The beech tree (the *Fagus silvatica* of Linnæus) is one of the most magnificent of the English trees, attaining, in about sixty or seventy years, in favourable situations, a height of from 70 to 100 feet, and its trunk a diameter of five feet. The wood, when green, is the hardest of British timbers, and its durability is increased by steeping in water; it is chiefly used by cabinet makers, coopers, coach builders, and turners.

Digitized by Google

BEECH NUT OIL. A mild oil obtained by pressure from the beech nuts. It is used in cooking, and substituted for olive oil.

BEER. (*Bière*, Fr.; *Bier*, Germ.) The fermented infusion of malted barley, flavoured with hops, constitutes the best species of beer; known also as ale, bitter ale, porter, or brown stout, according to its varied flavour, colour, and strength. But there are many beverages of inferior quality to which the name of beer is given, such as spruce beer, ginger beer, &c., all of which consist of a saccharine liquor partially advanced into the vinous fermentation, and flavoured with peculiar substances.

The ancients were acquainted with beer, and the Romans gave it the appropriate name of Cerevisia (*quasi Ceresia*), as being the product of corn, the gift of Ceres. The most celebrated liquor of this kind in the old time was the Pelusian potation, so called from the town where it was prepared, at the mouth of the Nile. Aristotle speaks of the intoxication caused by beer, and Theophrastus justly denominated it the wine of barley. We may indeed infer, from the notices found in historians, that drinks analogous to beer were in use among the ancient Gauls, Germans, and, in fact, almost every people of our temperate zone; and they are still the universal beverage in every land where the vine is not an object of rustic husbandry.

The manufacture of beer may be conveniently considered under three heads.

1. An examination of the natural productions which enter into its composition: barley and hops.

2. The preparation which one of those materials, barley, must undergo in the process of malting.

3. The formation of a saccharine liquor, or wort, and imparting to it the peculiar flavour and properties of the hop, with the fermentation, fining, ripening, and preservation of the beer.

1. The Materials.

1. Barley (*Hordeum*).—Barley, wheat, maize, and several other kinds of grain, are capable of undergoing those changes which develope the saccharine principle from which beer can be made; but the first-named is by far the most fit, and in this country is almost exclusively used. There are two species of barley, the *Hordeum vulgare*, or common barley, having its corns arranged in two rows on its spikes; and the *Hordeum hexastichon*, in which three seeds spring from one point, so that its double row has apparently six corns. The former is the proper barley, and is much the larger sized grain. The latter is little known in England, but is much cultivated in Scotland under the name of bere, or big, being a hardy plant, adapted to a colder climate. Big is a less compact grain than barley; the weight of an imperial bushel (2218·192 ins.) of the former being only about 48 lbs., while that of the latter will be from 52 to 56 lbs. Their constituents are, however, very similar.

The quality of barley is much influenced by the soil on which it is grown; the best being from a light calcareous soil, or that known by farmers as good turnip land; and crops of excellent quality are also grown on a rich loam. Much also depends on the seed, the climate, and the care of the husbandman in the harvesting, stacking, and thrashing at the proper season. The barley should have a thin, bright, clean, wrinkled husk, closely adhering to a plump well-fed kernel, which, when broken, appears white and chalky, with a full uninjured germ of a pale yellow colour.

If it breaks hard and flinty, it should be avoided; and although not in a proper condition for malting until it has sweated or seasoned in the stack or mow, care must be taken that it has not heated so as to destroy the vitality of the germ. Mixed or uneven samples should also be avoided, as it is important that all should grow simultaneously or evenly on the floors.

By chemical analysis, 100 parts of barley-meal appear to consist of:—

Gluten	3·76	Albumen	2·23
Starch	72·00	Phosphate of lime	0·25
Sugar	5·60	Water	10·00
Gum	5·00	Loss	1·16

Another analysis gives—

Gluten	3.52	Phosphates	0.24
Hordeum, or starch and gluten intimately combined	67·18	Oil	0·30
		Vegetable fibre	7·29
Sugar	5·21	Water	9 37
Gum	4·62	Loss	1·12
Albumen	1·15		

Digitized by Google

Hermstadt gives the mean of several analyses of barley to be:—

Gluten	4·92	Oils	0·35
Starch	60·50	Phosphates	0·36
Sugar	4·66	Husk	11·56
Gum	4·51	Water	10.48
Albumen	0·35	Loss	2·31

Proust thought he had discovered in barley a peculiar principle, to which he gave the name of Hordeine, which he separated from the starch by the action of both cold and boiling water. He found that, by treating barley-meal successively with water, he obtained from 89 to 90 parts of a farinaceous substance, composed of from 32 to 33 of starch, and from 57 to 58 of hordein; his analysis also gives, gluten, 3·0; sugar, 5·0; gum, 4·0; and resinous extract, 1·0.

Dr. T. Thomson gives no hordeine, but the starch as 88 per cent., sugar 4.

Einhof gives the constituents of barley as 70·05 flour, 18·75 husk, and 11·20 water.

The hordeine of Proust is a yellowish powder, contains no azote, and is, therefore, dissimilar to gluten. In the process of malting the proportion of hordeine is greatly diminished by its conversion into starch and sugar, so that many chemists view hordeine as only an allotropic condition of starch: but the subject will evidently bear yet more extended and careful research.

2. Hops (*Humulus lupulus*).—The female flowers, or catkins, of a dicœcious plant belonging to the natural order Urticaceæ; which grows wild in many English hedgerows, but requires the most careful cultivation to produce the highly odoriferous and cordial properties so valued by the brewer. The plant springs up annually from the old roots in April, flowers the latter end of June, and ripens towards the end of August and in September, when they are gathered, dried, and packed very tightly in pockets, or bags, for preservation and use. Hops are grown to the greatest extent in the counties of Kent and Sussex; but a strong hop is also grown in the north clay district of the county of Nottingham, and a very grateful mild hop in the Worcestershire district.

The flavour of the Golding, or Farnham hop, a district in Surrey, is rich, and in high estimation; but the plant is one of the most tender cultivated, the flower small, but heavy with the farina, and the crop very uncertain.

The Canterbury grape-hop is much cultivated in the districts of Kent and Sussex, and deservedly esteemed as a good useful hop.

The Flemish plant produces a large flower, but of light weight and of inferior flavour; it is considered a hardy kind, and very productive.

Hops require a rich soil, well manured and cleaned, a sunny aspect, and to be sheltered from the east winds, which not only check the growth of the plants, but cause them to be infested with vermin, which are sometimes so numerous as to destroy nearly the entire crop. The flower, during the ripening season, is also sometimes attacked by the red or blue mould, which often consumes a considerable portion of the farina, and may be discovered by the strig of the flower being bare of leaf.

The catkins or strobils of the hop consist of the scales, or large and persistent bracts, which, in the early period of their growth, are of a light green colour (afterwards changing to a pale yellow), at the bottom of which are small, round seeds, that, when ripe, have a hard shell of a brown or reddish colour. They are imbedded in the farina, or yellow powder, which is the most valuable part of the hop.

No hop should be gathered till the seed is matured; not for the sake of the seed itself, but the nectarium, or farina, will be in larger particles, and its essential aromatic and bitter qualities more perfectly developed when ripe. Good hops, when rubbed in the hand, leave an oily, or resinous, and rather clammy feeling, with a pungent and gratifying odour; the scales should also be even in colour, and without any green specks, or any appearance of mould on the strig, or small stem of the flower.

The drying of the hop is an important part of its management, and requires great care; it is performed in kilns, in Sussex, termed oast-houses. The heat should be moderate and regular, in no case exceeding 120° F., as to over-dry them would injure the flavour, and if not sufficiently dry they are liable to become mouldy. The general practice is to try the strig or stalk of the flower, which if it snaps from brittleness is sufficiently dried, but if it bends without breaking more drying is necessary.

The packing has also much influence in the preservation of the valuable but volatile aroma. The finer flavoured and pale hops are well rammed into sacks of fine canvas, called pockets, which weigh about 1½cwt. each; the stronger and dark-coloured hops into sacks of a coarser texture, called hop bags, and weigh from 2½ cwts. to 3 cwts. each.

Digitized by Google

If intended for export, the bags are sometimes subjected to the action of the hydraulic press; and if not required for immediate use, the simple screw press may be used with great advantage.

Dr. Ives first directed attention to the yellow pulverulent substance that has been alluded to as the farina, or pollen, and is technically known as the "condition" of the hop, which in good samples will amount to one-sixth of their weight. This powder bears some resemblance to lycopodium; and its analysis by Dr. Ives gives, tannin, 4·16; extractive, 8·33; bitter principle, 9·16; wax, 10·00; resin, 30·00; lignin, 38·33; and loss, 0·02. About 65 per cent. of the farina is soluble in alcohol, and the solution, distilled with water, leaves a resin amounting to 52·5 per cent., which has no bitter taste, and is soluble in alcohol or ether. The distillate from which the resin has thus been separated contains the bitter principle, which has been called "lupuline" (by Payen and Chevallier), mixed with a little tannin and malic acid.

To obtain this in a state of purity, the free acid must be saturated with lime, the solution evaporated to dryness, and the residuum treated with ether, which removes a little resin; after which the lupuline is dissolved out by alcohol, leaving the malate of lime. On evaporating the alcohol, the lupuline remains, weighing from 8·3 to 12·5 per cent. It is sometimes white, or slightly yellowish, and opaque, sometimes orange-yellow and transparent.

At ordinary temperatures it is inodorous, but when heated emits the peculiar smell and possesses the characteristic taste and bitterness of the hop. Water dissolves it in the proportion of about 1 part to 20, or 5 per cent., and acquires a yellow colour. It is quite soluble in alcohol and slightly so in ether.

Lupuline is neither acid nor alkaline, nor is it acted upon by solutions of the metallic salts; it contains apparently no azote, but only an empyreumatic oil.

The analysis of Payen and Chevallier gives the following:—Volatile oil, 2·00; lupuline, 10·30; resin, 55·00; lignin, 32·00; loss, 0·70. There are also traces of fatty, astringent, and gummy matters, malic and carbonic acids, and various salts.

The volatile oil was procured by Dr. Wagner by distilling fresh hops with water. It constituted about 8 per cent. of the air-dried flowers, it possessed a clear brownish-yellow colour, had an acrid taste and a strong odour of the hop. Its specific gravity is about 0·910; it is partially soluble in water, but more so in alcohol and ether, and becomes resinified by keeping. The tannin of the hop is also important in brewing, as it serves to precipitate the nitrogenised or albuminous matter of the barley, and assist the clearing of the liquor. Ives thought the scales of the hop, when freed from the yellow powder, contained no principles analogous to it; but it is almost impossible to free them entirely from the lupulinic grains; and Payen and Chevallier found the same principles in the different parts of the hop, but in different proportions.

2. The Preparation of the Barley by the Process of Malting.

In this process (for the conduct of which we refer to the article Malting) the raw grain is steeped in cisterns of water until it has imbibed sufficient to cause it to germinate; it is then spread on the floor of the malt-house, and frequently turned, until the germination has advanced to the stage when the plumula is about to make its appearance, and its further germination is stopped by being rapidly dried on the malt-kiln.

During germination a remarkable change has taken place in the substance of the grain. The glutinous constituent has almost entirely disappeared, and is supposed to have passed into the matter of the radicles, or roots, which during the process will have grown rapidly to nearly one and a half the length of the grain, while a portion of the starch is converted into sugar and mucilage.

The change is similar to that which starch undergoes when dissolved in water and digested in a heat of about 160° F. along with a little gluten. The thick paste becomes gradually liquid, transparent and sweet tasted, and the solution contains now sugar and gum, with some unaltered starch. The gluten suffers a change at the same time, and becomes acescent, so that only a certain quantity of starch can thus be converted by a quantity of gluten.

By the artificial growth upon the malt-floor all the gluten and albumen present in barley are not decomposed, and only about one-half of the starch is converted into sugar, as a continuance of the germination would exhaust the grain, and the valuable products would be taken up by the growth of the roots and stems of the plant. It is, therefore, the chief art of the maltster to regulate the germination and stop it at the point when the utmost conversion is attained with the least loss. This is generally considered to be done when the plumula, technically known as the acrospire, has advanced two-thirds the entire length of the grain, starting from the germ and proceeding under the skin toward the other end of the grain, beyond which it must never be suffered to protrude; the conversion of the hordeine into starch and sugar keeping

Digitized by Google

pace with the growth of the acrospire, and being thus prepared for its nearly complete conversion in the subsequent operations of the brewer.

Malt is generally distinguished by its colour — as pale, amber, brown, or black malt —arising from the different degrees of heat and management in the process of drying. The first is produced when the highest heat to which it has been subjected is from 90° to 100° F., the amber-coloured when the heat has been raised to 120° or 125°, and the brown at a heat of from 150° to 170°. The black malt, commonly called patent malt, is prepared by roasting in cylinders, like coffee, at a heat of from 360° to 400°, and is the only legal colouring matter that may be used in the brewing of porter.

The action of the kiln in drying is not confined to the mere expulsion of the moisture from the germinated seeds, but it serves to convert into sugar a portion of the starch which remained unchanged, not only by the action of the gluten upon the fecula at an elevated temperature, but also by the species of roasting which the starch undergoes, which renders it of a gummy nature. We have a proof of this, if we dry one portion of the malt in a naturally dry atmosphere, and another portion in a moderately warm kiln; we shall find the former yield a less saccharine extract than the latter. Moreover, kiln-dried malt has a peculiar, agreeable, and faintly-burned taste, probably from a small portion of empyreumatic oil formed in the husk, which not only imparts its flavour to the beer, but also contributes to its preservation.

As the quality of the malt depends much on that of the barley, so its skilful preparation has the greatest influence both on the quantity and quality of the worts made from it. If the germination has been imperfect or irregular, a portion of the malt will be raw, and too much of its substance remain unchanged and flinty; if it has been pushed too far, a part of the extractible matter is wasted.

If not thoroughly dried, the malt will not keep, but becomes soft and liable to mildew; and if too highly kiln-dried, a portion of its sugar will be caramelised and become bitter.

Good malt possesses the following characteristics: — The grain is round and full, breaks freely between the teeth, and has a sweetish taste, an agreeable smell, and is full of a soft flour from end to end. It affords no unpleasant flavour on being chewed; is not hard, so that when drawn along an oaken board across the fibres it leaves a white streak like chalk. It swims upon water, while unmalted barley sinks in it.

The bulk of good malt exceeds that of the barley from which it is made by from 5 to 8 per cent., but at the same time it becomes lighter in weight, 100 lbs. of good barley, judiciously malted, weighing, after being dried and screened, no more than about 80 lbs., the loss being about 12 per cent. of water, 5 per cent. waste, and about 3 per cent. by the growth of the roots, which, in drying, have been rendered brittle, and are removed by passing the malt over a wire screen.

The change which the barley has undergone by malting will be readily seen in the following comparative analysis by Proust: —

	Barley.	Malt.
Gluten	3	1
Hordein	55	12
Starch	32	56
Sugar	5	15
Mucilage	4	15
Resin	1	1
	100	100

We thus see the amount of the convertible starch and sugar has been nearly doubled at the expense of the hordein, a portion of which has also passed into the condition of mucilage, or a soluble gum, while the gluten is much diminished.

The researches of Payen and Persoz show there is also a new proximate principle formed during the malting, which may be considered as a residuum of the gluten, or vegetable albumen, in the germinating grain.

If we moisten the malt flour for a few minutes with cold water, press it out strongly, filter the solution, and heat the clear liquid in a water-bath to the temperature of 158°, the greater part of the albuminous azotised substance will be coagulated, and should be separated by a fresh filtration; after which the clear liquid is to be treated with alcohol, when a flocky precipitate appears, to which has been given the name of diastase. To purify it still further, especially from the azotised matter, we should dissolve it in water, and precipitate again with alcohol. When dried at a low temperature it appears as a solid white substance, which contains no azote, is insoluble in alcohol, but dissolves in water and proof spirit. Its solution is neutral and tasteless; it changes with greater or less rapidity according to the temperature, and becomes

Digitized by Google

sour at a temperature from 149° to 167°. It has the property of converting starch into gum, or dextrine (so called by the French chemists, from its polarising light to the right hand, whereas common gum does it to the left) and sugar; and, indeed, when sufficiently pure, the diastase operates with such energy that one part of it disposes 2000 parts of dry starch to that change, but it operates the quicker the greater its quantity.

Whenever the solution of diastase with starch is heated to the boiling point, it loses the converting property.

One hundred parts of the starch solution from good malt appear to contain about one part of this substance, which is of the greatest importance in effecting the further changes which take place in the process of brewing.

3. The Formation of a Saccharine Liquid, or Wort,

from the malt and hops, and production of the finished beer, is the province of the brewer; and the process will be found at length under the article Brewing.

The peculiar properties contained in wort do not exist ready formed in malt, but are the result of the joint action of water and heat which is employed in the initiatory process of the brewer on that substance, and is termed the mashing.

The Mashing.—This operation requires the greatest care, as on it, almost as much as on the malt employed, depends the character of the liquor.

Payen and Persoz, already alluded to, show that the mucilage formed by the reaction of malt upon starch may be either converted into sugar or be made into a permanent gum, according to the temperature of the water in which the materials are digested. We take of pale barley malt, ground fine, from 6 to 10 parts, and 100 parts of starch; we heat, by means of a water-bath, 400 parts of water in a copper to about 80° F.; we then stir in the malt, and increase the heat to 140° F., when we add the starch, and stir well together. We next raise the temperature to 158°, and endeavour to maintain it constantly at that point, or, at least, to keep it within the limits of 167° on the one side and 158° on the other. At the end of twenty or thirty minutes the original milky and pasty solution becomes thinner, and soon after as fluid nearly as water. This is the moment when the starch is converted into gum or dextrine. If this merely mucilaginous solution, which seems to be a solution of gum with a little liquid starch and sugar, be suitably evaporated, it may serve for various purposes in the arts to which gum is applied; but, with this view, it must be quickly raised to the boiling point, to prevent further change. If we wish, on the contrary, to produce a saccharine fluid, such as the wort for beer, we must maintain the temperature at between 158° and 167° for three or four hours, when the greatest part of the starch will have passed into sugar, and by evaporation of the liquid at the same temperature, a starch syrup may be obtained like that procured by the action of sulphuric acid upon starch.

In the operation of mashing, the finished and mellowed malt, having been well cleansed from all extraneous matters by screening, is coarsely ground, or better if only crushed between iron rollers, as is now generally practised. It is then gradually mixed with water in the mash-tun, at the proper heat, and intimately blended by stirring with the mashing-rakes, so that it may be uniformly moistened and no lumps remain. After being allowed some time to stand and settle, the liquor is drawn off, and more water at a higher temperature is added, again intimately blended with the malt,—now termed the goods,—again allowed to rest, and drawn off; the operation being repeated until the complete exhaustion of the saccharine and amylaceous substances of the malt is effected.

We can now see, from Payen and Persoz's experiment just given, the temperature at which the liquor ought to be maintained in this operation; namely, the range between 158° and 167°; and it has been ascertained, as a principle in mashing, that the best and soundest extract of the malt is to be obtained, first, by beginning to work with water at the lowest of these heats, and to conclude with water at the highest; secondly, not to operate the extraction at once with the whole of the water that is to be employed, but with separate portions and by degrees.

The first portion has the task of penetrating equally the crushed malt, extracting the more soluble ingredients and subjecting the dissolved starch to the action of the diastase and free sugar; the second and further portions are for the purpose of converting the remaining starch and completing the extraction of all the available products. By this means also the starch is not allowed to run into a cohesive paste, or, as it is termed, "lock up the goods," and the extract is more easily drained from the mass, and comes off a nearly limpid wort. The thicker, moreover, or the less diluted the mash is, so much the easier is the wort fined in the boiler or copper by the coagulation of the albuminous matter. These principles indicate the true mode of conducting the mashing process, but different kinds of malt require a different treatment; pale and

Digitized by Google

slightly kilned malt requires a somewhat lower heat than malt highly kilned, because the former is more ready to become pasty, and, for the same reason, needs a more leisurely infusion than the latter; and this is still more applicable to the case of a mixture of raw grain with malt, for it requires still gentler heats and more cautious treatment.

It is quite practicable to obtain from 1 part of malt and 8 parts of barley, a wort precisely similar to that procured from 9 parts of pure malt alone. But, of course, this could not be done without modifying considerably the process of mashing; and it happens, unfortunately, that the practice of the present day, amongst brewers, is to maintain, as closely as possible, one uniform system of mashing, whatever may be the nature or quality of the malt employed. Thus a difference in the malt is made to produce a difference in the wort, and all the energy and skill of the practical brewer are sometimes insufficient to compensate for the alterations which this difference induces in the subsequent working of the beer. With a regular and certain composition, as to the constituents of his wort, the operations of the brewer would assume a fixed and definite character, which, at present, they are very far indeed from possessing; and by which he not unfrequently suffers the most severe pecuniary loss and mental anxiety. With the exception of a trifling quantity of vegetable albumen, the only solid ingredients of beer-wort are dextrine and sugar; the latter of which ferments with great ease and rapidity, whilst the dextrine, though capable of fermentation, enters into the process only with difficulty, and requires, for its successful termination, not only much more yeast, but also a much higher temperature in the fermenting vat. At the same time, it is this very sluggishness in the fermentative quality of dextrine which is essential to the production of good beer; for, with sugar alone, the fermentation cannot be checked at ordinary temperatures, until the full measure of its decomposition has taken place, and it has become either a vapid admixture of alcohol and water, or, by the absorption of oxygen, is resolved into vinegar. It is indeed a notorious fact, that beer made with sugar will not keep so well as that made from malt; though, for rapid consumption, the use of sugar is, under some circumstances, to be commended, more especially on the small scale and in cold weather. The peculiarity of dextrine is, however, as we have stated, to undergo fermentation only with difficulty and by slow degrees; hence its decomposition spreads over a long space of time, and, in very cold weather, amounts to nothing; so that for months, or even years, after all the sugar of the wort has been destroyed, the evolution of carbonic acid gas from the still fermenting dextrine, keeps up a briskness and vitality in the beer; and, by excluding oxygen, all chance of acidification is shut off. A perfect beer-wort should therefore have reference to the period of its consumption: if this be speedy and pressing, the proportion of sugar ought to be large; if remote, the dextrine should greatly predominate. Under the first condition, the attenuation would proceed quickly, and, provided the temperature of the fermenting vat was not allowed to exceed 78°, the beer would soon cleanse and become ripe and bright; under the second, the attenuation in the vat would be slow and trifling, and require, perhaps, several years for its completion in the cask. Nevertheless, if the attenuation in the vat had gone on to the complete destruction of all the sugar, this kind of beer would prove in the end both the better and more healthy beverage of the two; for by the mode of its formation the presence of œnanthic ether or fusel oil is avoided. The importance therefore of placing in the hands of the brewer a means of determining the relative amounts of sugar and dextrine in his wort is sufficiently obvious. Now, this may be done in two ways; either by ascertaining, in wort of a determinate strength, the proportion of the one or the other of these substances. The dextrine is easier of calculation than the sugar, in a rough or approximate way; but the sugar can be determined with much more minute accuracy than the dextrine. Yet, in practice, the former plan is preferable, from its simplicity, as we shall proceed to show. If, to a certain volume of strong wort (say of 30 lbs. per barrel), we add an equal amount of alcohol or spirits of wine, the whole of the dextrine will precipitate as a dense coagulum; and by examining the bulk of this deposit in the tube, its weight may be inferred pretty nearly if the tube has been previously graduated, so as to indicate, from actual experiment, the weight of the different measures of the coagulated dextrine. With weaker wort, more alcohol must be used, and with a denser wort, less alcohol, — the relations of which to each other may easily be kept recorded on a small card or scale affixed to the tube. This instrument is very easy of application, and has been found extremely useful to more than one practical brewer of the present day; and the accompanying record of brewing operations has reference to this mode of analysing wort. The determination of sugar in wort is best effected by boiling 100 grains of it with about half a pint of the following solution, and collecting and weighing the red-coloured precipitate which ensues, — every three grains of which indicate one grain of grape-sugar in the wort.

Grape-sugar Test Solution.

Sulphate of copper in crystals	100 grains.
Bitartrate of potash	200 „
Carbonate of soda in crystals	800 „
Boiling water, one pint, or	8750 „

First dissolve the sulphate of copper, then the bitartrate of potash, after which add the carbonate of soda, and filter if necessary. This solution is not affected when boiled with cane-sugar, dextrine, gum, or starch.

We have retained from Dr. Ure's original article the result of two brewings, taken from one mash at two different periods, and analysed to determine their relative contents of dextrine and sugar, according to the tube or alcohol process:—March 28th, 1851, proceeded to mash for experimental brewings; weather clear and open; thermometer outside at 51°,—in fermenting room 58°; difference between wet and dry bulb, 5·750°; barometer, 39·4 inches. Composition of the malt:—Moisture, 6·1; insoluble matter, 27; extract, 66·9. Quantity of malt employed, 70 bushels; of water at 180° F., 700 gallons; made the mixture with a common mashing-oar, and finished in 15 minutes. One hour afterwards, drew off 200 gallons of wort; and three hours from commencing to mash, drew off 200 gallons more,—continuing the mash for table-beer wort. The first-drawn wort contained 7·5 parts of dextrine to 1 of sugar; the second, 6·3 parts of dextrine, 2·2 of sugar;—their densities were, respectively, 30 and 36·5 lbs. per barrel. They were each boiled separately, with relative amount of hop,—the first having 30 and the second 36½ lbs. added; and the boiling in each case was kept up for three hours. At the end of this time both were cooled and diluted with water to a gravity of 27½ lbs. per barrel, and 250 gallons of each let down into separate fermenting-vats placed side by side; after which, they both received three quarts of good yeast,—the temperature being at 68° F. Two hours afterwards, the following observations commenced:—No. 1 being the wort containing 7·5 parts of dextrine to 1 of sugar, and No. 2 the wort having 6·3 of dextrine to 2·2 of sugar.

1851.	No. 1.	Temp.
March 28, 5 P.M.	No action	67·5°
„ „ 10 P.M.	Light thin cream	67·5
„ 29, 9 A.M.	White head	70·0
„ „ 6 P.M.	Fine white head	71·0
„ 30, 9 A.M.	Thick tough head	74·0
„ „ 6 P.M.	Tough brown head	75·0
„ 31, 2 P.M.	Ferment well roused up	75·0
	Attenuation of No. 1.	8·5
April 2, 2 P.M.	(Skimmed off yeast)	10·0
„ 11, 2 P.M.	„ „	15·0
„ 13, 2 P.M.	„ „	15·5
	No. 2.	
March 28, 5 P.M.	No action	68·0
„ „ 10 P.M.	Fine white head	70·0
„ 29, 9 A.M.	Thick yellow head	74·0
„ „ 6 P.M.	Fine tough brown head	77·0
„ 30, 9 A.M.	High roused-up rocky head	77·0
„ „ 6 P.M.	In rapid fermentation	76·5
„ 31, 2 P.M.	Throws up much yeast (skimmed off yeast)	76·0
	Attenuation of No. 2	12·7
April 2, 2 P.M.	„ „	15·5
„ 11, 2 P.M.	„ „	17·5
„ 13, 2 P.M.	„ „	18·2

The temperature of both had now fallen to 69° F., though each had been roused repeatedly; the yeast was therefore again skimmed off, and the beer run into barrels, and filled up with reserved wort three times a day as it worked over. On April the 18th the barrels were closed, having then lost, by attenuation—No. 1, 16·2 lbs., and No. 2, 19·6 lbs. Six weeks afterwards these ales were examined;—No. 1 was found muddy and unpleasant; whilst No. 2 had a fine fragrant aroma, a brisk, lively appearance, and was perfectly bright. On January 2nd, 1852, the casks were again examined;—No. 1 had now lost 17·9 lbs., and was bright, rich, and fine flavoured;

Digitized by Google

whilst No. 2, though bright and pleasant, had contracted a little acidity, and was becoming flat: it had lost, in all, 21½ lbs.

Two similar experiments, made about the same time in another quarter, gave almost exactly the same results; and, consequently, there can be little doubt that, where a quick sale and rapid consumption of beer can be ensured, the great object of the brewer should be to convert as much of the dextrine of his wort into sugar as is proportional to the rapidity of that consumption; whereas, for beer intended to keep, the opposite practice should be followed.

The conversion of any given amount of the dextrine wort into sugar may be effected either by keeping up the temperature of the mash-tun, and prolonging the operation of mashing; or, which is better and simpler, by merely preserving the wort for a few hours at a heat of 165° F., either in the underback or any other convenient vessel. We have found from experiment that a wort which when run out from the mash-tun had only 3 parts of sugar to 16 of dextrine, became by 10 hours' exposure to a heat of 165° converted almost altogether into sugar, — the proportions then being 17·8 of sugar to 1·2 of dextrine.

A very important part of the duty of a brewer should therefore be, first, the determination of the relative amounts of dextrine and sugar required to suit the taste of his customers, or the circumstances of the market, and next, the continued careful examination of his wort, so as to ensure that these proportions are regularly maintained; for by no other plan is it possible to ensure that certainty of result and uniformity of quality which are essential to the proper conducting of an expensive business like brewing. Far too little attention has hitherto been given to the fluctuating qualities of beer-wort; in warm weather, this wort should probably contain at least twice as much dextrine as in winter; yet this is the very period when, from the increased temperature of the air and materials, the largest quantity of sugar must be formed by those who mash upon a fixed and unvarying principle. Hence the proneness of the wort to ferment violently in summer is still further increased by the presence of an extra proportion of sugar; — whereas prudence would suggest, under such circumstances, a predominance of dextrine, and seek to effect this purpose by a low temperature in the mash-tun, and by shortening the period of mashing. As a general rule, in the management of wort, more sugar is requisite where small quantities are brewed at a time, than where large operations are conducted, for the loss of heat is relatively larger in small masses than in large ones; and, from what has been stated, it must be apparent, that, as the fermentation of dextrine is more easily checked by cold than that of sugar, the beer brewed in trifling quantities could not preserve a fermentative temperature, but would become chilled and dead from the excessive radiation of caloric, unless a principle existed in it capable of fermentation at the most ordinary temperatures of this country. If, therefore, beer wort consisting chiefly of dextrine be fermented in very cold weather, or with an insufficiency of yeast, or if the temperature happen to rise too high, so as to destroy or impair the fermentative power of the yeast, then a dull languid action will ensue, accompanied by what has been called the viscous fermentation, and the beer becomes permanently ropy, and is spoiled.

Although, clearly, it would be impossible to lay down any specific rule for the proper proportion of dextrine and sugar in beer wort, yet there could be no difficulty in each brewer determining for himself, and for the conditions of quantity, time of sale, time of year, and other contingencies, the requisite ratio to be established in his own case; and, as we have shown, nothing can be simpler than the means proposed for ascertaining the composition of wort.

The quantity of extract, per barrel weight, which a quarter of malt yields to wort, amounts to about 84lbs. The wort of the first extract is the strongest; the second contains, commonly, one-half the extract of the first; and the third, one-half of the second; according to circumstances.

To measure the degrees of concentration of the worts drawn off from the tun, a particular form of hydrometer, called a saccharometer, is employed, which indicates the number of pounds weight of liquid contained in a barrel of 36 gallons imperial measure. Now, as the barrel of water weighs 360lbs., the indication of the instrument, when placed in any wort, shows by how many pounds a barrel of that wort is heavier than a barrel of water; thus, if the instrument sinks with its poise till the mark 10 is upon a line with the surface of the liquid, it indicates that a barrel of that wort weighs ten pounds more than a barrel of water. See SACCHAROMETER.

Or, supposing the barrel of wort weighs 396lbs., to convert that number into specific gravity, we have the following simple rule: —

$$360 : 396 :: 100 : 1{\cdot}100;$$

at which density the wort contains about 25 per cent. of solid extract.

Digitized by Google

By the mashing operations before described, the malt is so much exhausted that it can yield no further extract useful for strong beer or porter. A weaker wort might no doubt still be drawn off for small beer, or for contributing a little to the strength of the next mashing of fresh malt. But this I believe is seldom practised by respectable brewers, as it impoverishes the grains which they dispose of for feeding cattle.

The wort should be transferred into the copper, and made to boil as soon as possible, for if it remains long in the under-back it is apt to become acescent. The steam moreover raised from it in the act of boiling serves to screen it from the oxygenating or acidifying influence of the atmosphere. Until it begins to boil, the air should be excluded by some kind of cover.

Dr. Piesse, in 1840, read a paper before the Chemical Society, showing that much extract was left in the malt after brewing, and that it was this matter, which was convertible into sugar, which gave its feeding qualities to the 'grains.' It was shown that the malt, after the first wort was drawn off, still contained a portion of starch which was not converted into sugar, and that the presence of diastase was necessary to effect this conversion. As diastase is very soluble, there was none of course left in the infused malt. It is, therefore, recommended by Dr. Piesse, that malt containing diastase should be added to the second wort. 'In brewing 30 quarters, I should take 29 quarters for the first mash and add the remaining quarter to the second, by which all the starch it was contended would be converted into sugar. To prevent the access of air—which tends to induce acidity—to the wort, it is suggested that a board the size of the back in which it is contained should float on the surface of the fluid. (*Transactions of the Chemical Society*, 1841.)

The Boiling.—The wort drawn from the mash-tun, whenever it is pumped into the copper, should receive its allowance of hops. Besides evaporating off a portion of the water, and thereby concentrating the wort, boiling has a twofold object. In the first place, it coagulates the albuminous matter, partly by the heat, and partly by the principles in the hops, and thereby causes a general clarification of the whole mass, with the effect of separating the muddy matters in a flocculent form. Secondly, during the ebullition, the residuary starch and hordeine of the malt are converted into a limpid sweetish mucilage, the *dextrine* above described, while some of the glutinous stringy matter is rendered insoluble by the tannin principle of the hops, which favours still further the clearing of the wort. By both operations the keeping quality of the beer is improved. This boil must be continued some time; a longer time for the stronger, and a shorter for the weaker beers. There is usually one-seventh or one-sixth part of the water dissipated in the boiling copper. From one to three hours' boil is deemed long enough in many well-conducted breweries.

Many prefer adding the hops when the wort has just come to the boiling point. Their effect is to repress the passage into the acetous stage, which would otherwise inevitably ensue in a few days. In this respect, no other vegetable production hitherto discovered can be a substitute for the hop. The odorant principle is not so readily volatilised as would at first be imagined; for when hop is mixed with strong beer wort, and boiled for many hours, it can still impart a very considerable degree of its flavour to weaker beer. By mere infusion in hot beer or water, without boiling, the hop loses very little of its soluble principles. The tannin of the hop combines, as we have said, with the vegetable albumen of the barley, and helps to clarify the liquor. Should there be a deficiency of albumen and gluten, in consequence of the mashing having been done at such a heat as to have coagulated them beforehand, the defect may be remedied by the addition of a little gelatine to the wort copper, either in the form of calf's foot, or of a little isinglass. If the hops be boiled in the wort for a longer period than 5 or 6 hours, they lose a portion of their fine flavour; but if their natural flavour be rank, a little extra boiling improves it. Many brewers throw the hops in upon the surface of the boiling wort, and allow them to swim there for some time, that the steam may penetrate them, and open their pores for a complete solution of their principles when they are pushed down into the liquor.

The quantity of hop to be added to the wort varies according to the strength of the beer, the length of time it is to be kept, or the heat of the climate where it is intended to be sent. For beer 4½ lbs. of hops are required to a quarter of malt; but when it is to be highly aromatic and remarkably clear, and for the stronger kinds of ale and porter, the rule, in England, is to take a pound of hops for every bushel of malt, or 8 lbs. to a quarter. Common beer has seldom more than a quarter of a pound of hops to the bushel of malt.

The Cooling.—The contents of the copper are run into what is called the hop-back, on the upper part of which is fixed a drainer, to keep back the hops. In some arrangements a pump is placed in the hop-back, for the purpose of raising the wort to the coolers, usually placed in an airy situation upon the top of the brewery. Two coolers are

Digitized by Google

indispensable when we make two kinds of beer from the same brewing, and even in single brewings, called *gyles*, if small beer is to be made. One of these coolers ought to be placed above the level of the other. As it is of great consequence to cool the worts down to the fermenting pitch as fast as possible, various contrivances have been made for effecting this purpose. The common cooler is a square wooden cistern, about 6 inches deep, and of such an extent of surface that the whole of one boil may only occupy 2 inches, or thereabouts of depth in it. For a quantity of wort equal to about 1500 gallons, its area should be at least 54 feet long and 20 feet wide. The seams of the cooler must be made perfectly water-tight and smooth, so that no liquor may lodge in them when they are emptied. The utmost cleanliness is required, and an occasional sweetening with lime-water.

The hot wort reaches the cooler at a temperature of from 200° to 208°, according to the power of the pump. Here it should be cooled to the proper temperature for the fermenting tun, which may vary from 54° to 64°, according to circumstances. The refrigeration is accomplished by the evaporation of a portion of the liquor; it is more rapid in proportion to the extent of the surface, to the low temperature and the dryness of the atmosphere surrounding the cooler. The renewal of a body of cool dry air, by the agency of a fan, may be employed with great advantage. The cooler itself must be so placed that its surface shall be freely exposed to the prevailing wind of the district, and be as free as possible from the eddy of surrounding buildings. It is thought by many, that the agitation of the wort during its cooling is hurtful. Were the roof made movable, so that the wort could be readily exposed, in a clear night, to the aspect of the sky, it would cool rapidly by radiation, on the principles explained by Dr. Wells, in his "Essay on Dew," and more recently by M. Melloni.

When the cooling is effected by evaporation alone, the temperature falls very slowly, even in cold air, if it be loaded with moisture. But when the air is dry, the evaporation is vigorous, and the moisture exhaled does not remain incumbent on the liquor, as in damp weather, but is diffused widely in space. Here we can understand how wort cools so rapidly in the spring and autumn, when the air is generally dry, and even more quickly than in winter, when the air is cooler, but loaded with moisture. In fact, the cooling process goes on better when the atmosphere is from 50° to 55°, than when it falls to the freezing point, because in this case, if the air be still, the vapours generated remain on the surface of the liquor, and prevent further evaporation. In summer the cooling can take place only during the night.

In consequence of the evaporation during this cooling process, the bulk of the wort is considerably reduced; thus, if the temperature at the beginning was 208°, and if it be at the end 64°, the quantity of water necessary to be evaporated to produce this refrigeration, would be nearly $\frac{1}{8}$th of the whole, putting radiation and conduction of heat out of the question. The effect of this will be a proportional concentration of the beer.

The period of refrigeration, in a well-constructed cooler, amounts to 6 or 7 hours in favourable weather, but to 12 or 15 in other circumstances. The quality of the beer is much improved by shortening this period; because, in consequence of the great surface which the wort exposes to the air, it readily absorbs oxygen, and passes into the acetous fermentation with the production of various mouldy spots—an evil to which ill-hopped beer is particularly liable. Various schemes have been contrived to cool wort, by transmitting it through the convolutions of a pipe immersed in cold water. The best plan is to expose the hot wort for some hours freely to the atmosphere and the cooler, when the loss of heat is most rapid by evaporation and other means, and when the temperature falls to 100°, or thereabout, to transmit the liquor through a zig-zag pipe, laid almost horizontally in a trough of cold water. The various methods described under REFRIGERATOR are more complex, but they may be practised in many situations with considerable advantage.

Whilst the wort reposes in the cooler, it lets fall a slight sediment, which consists partly of fine flocks of coagulated albumen combined with tannin, and partly of starch, which had been dissolved at the high temperature, and separates at the lower. The wort should be perfectly limpid, for a muddy liquor never produces transparent beer. Such beer contains, besides mucilaginous sugar and gum, usually some starch, which even remains after the fermentation, and hinders its clarifying, and gives it a tendency to sour. The wort contains more starch the hotter it has been mashed, the less hops have been added, and the shorter time it has been boiled. The presence of starch in the wort may be made made manifest by adding a little solution of iodine in alcohol to it, when it will become immediately blue. We thus see that the tranquil cooling of wort in a proper vessel has an advantage over cooling it rapidly by a refrigeratory apparatus.

When the wort is sufficiently cool, it is let down into the fermenting tun. In this transfer, the cooling might be carried several degrees lower, were the wort made to pass down through a tube inclosed in another tube, along which a stream of cold water

Digitized by Google

is flowing in the opposite direction. These fermenting tuns are commonly called *gyle-tuns*, or working tuns, and are either square or circular. In the great London breweries their size is such that they contain from 1200 to 1500 barrels. The quantity of wort introduced at a time must, however, be considerably less than the capacity of the vessel, to allow room for the head of yeast which rises during the process of fermentation; if the vessel be cylindrical, this head is proportional to the depth of the worts. In certain kinds of fermentation, it may rise to a third of that depth. In general, the fermentation proceeds more uniformly and constantly in large masses, because they are little influenced by vicissitudes of temperature; smaller vessels, on the other hand, are more easily handled.

The Fermentation.—The *general* view of fermentation will be found under that title. A few remarks on the fermentation peculiar to beer will alone be noticed in this place. During the fermentation of wort, a portion of its saccharine matter is converted into alcohol, and the wort thus changed is beer. It is necessary that this conversion of the sugar be only partial, for beer which contains no undecomposed sugar would soon turn sour, and even in the casks its alcohol undergoes a slow fermentation into vinegar. The amount of this excess of sugar is greater in proportion to the strength of the wort, since a certain quantity of alcohol, already formed, prevents the operation of the ferment on the remaining wort. Temperature has the greatest influence upon the fermentation of wort. A temperature of from 55° to 60° of the liquor, when that of the atmosphere is 55°, is most advantageous for the commencement. The warmth of the wort as it comes into the gyle-tun must be modified by that of the air in the apartment. In winter, when this apartment is cold, the wort should not be cooled under 64° or 60°, as in that case the fermentation would be tedious or interrupted, and the wort liable to spoil or become sour. In summer, when the temperature of the place rises to above 75°, the wort should be cooled, if possible, down to 55°, for which purpose it should be let in by the system of double pipes above mentioned. The higher the temperature of the wort, the sooner will the fermentation begin and end, and the less is it in our power to regulate its progress. The expert brewer must steer a middle course between these two extremes, which threaten to destroy his labours. In some breweries a convoluted pipe is made to traverse or go round the sides of the gyle-tun, through which warm water is allowed to flow in winter, and cold in summer, so as to modify the temperature of the mass to the proper fermenting pitch. If there be no contrivance of this kind, the apartment may be cooled by suspending wet canvas opposite the windows in warm weather, or warmed by kindling a fire in a small stove within it in cold weather.

When the wort is discharged into the gyle-tun, it must receive its dose of yeast, which has been previously mixed with a quantity of the wort, and left in a warm place till it has begun to ferment. This mixture, called *lobb*, is then to be put into the tun, and stirred well through the mass. The yeast should be taken from similar beer. Its quantity must depend upon the temperature, strength, and quantity of the wort. In general, one gallon of yeast is sufficient to set 100 gallons of wort in complete fermentation. An excess of yeast is to be avoided, lest the fermentation should be too violent, and be finished in less than the proper period of 6 or 8 days. More yeast is required in winter than summer; for, at a temperature of 50°, a double quantity may be used to that at 68°.

Six or eight hours after adding the yeast, the tun being meanwhile covered, the fermentation becomes active: a white milky-looking froth appears, first on the middle, and spreads gradually over the whole surface; but continues highest in the middle, forming a frothy elevation, the height of which increases with the progress of the fermentation, and whose colour gradually changes to a bright brown, the result, apparently, of the oxidation of the extractive contained in this yeasty top. This covering screens the wort from the contact of atmospheric air. During this time, there is a perpetual disengagement of carbonic acid gas, which is proportional to the quantity of sugar converted into alcohol. The warmth of the fermenting liquid increases at the same time, and is at a maximum when the fermentation has come to its highest point. This increase of temperature amounts to from 9° to 14° or upwards, and is the greater the more rapid the fermentation. But in general, the fermentation is not allowed to proceed so far in the gyle-tun, for after it has advanced a little way, the beer is *cleansed*—that is, drawn off into other vessels, which are large barrels set on end, with large openings in their top, furnished with a sloping tray for discharging an excess of yeast into the wooden trough, in which the *stillions* stand. These *stillions* are placed in communication with a store-tub, which keeps them always full by hydrostatic pressure, so that the head of yeast may spontaneously flow over, and keep the body of liquor in the cask clean. This apparatus will be explained in describing the brewery plant. See the *figures, infrà*.

It must be observed, that the quantity of yeast, and the heat of fermentation, differ

Digitized by Google

for every different quality of beer. For mild ale, when the fermentation has reached 75°, its first flavour begins; at 80° the flavour increases; at 85° it approaches the high flavour; at 90° it is high; but it may be carried to 100° and upwards, for particular purposes. A wort of 30 lbs. per barrel (sp. gr. 1·088), ought to increase about 15°, so that in order to arrive at 80°, it should be set at 65°. The quantity of yeast for such an ale should be from 2 to 3 lbs. per barrel. The higher the heat, the less yeast is necessary. If the heat of the fermentation should at any time fall, it must be raised by a supply of fresh yeast, well stirred in; but this practice is not advisable in general, because rousing the worts in the gyle-tun is apt to communicate a rank flavour of yeast to the ale. It is the practice of many experienced brewers to look every 2 hours into the gyle-tun, chiefly with the view of observing the progress of the heat, which is low at first, but afterwards often increases half a degree per hour, and subsequently declines, as the fermentation approaches its conclusion, till at length the heat becomes uniform, or sometimes decreases, before the fermentation is finished, especially where the quantity operated upon is small.

Some brewers recommend, when the fermentation is carried to its utmost period, to add about 7 lbs. of wheat or bean flour to a gyle-tun of 25 or 30 barrels at the time of *cleansing*, so as to quicken the discharge of the yeast by disengagement of more carbonic acid. The flour should be whisked up in a pail, with some of the beer, till the lumps are broken, and then poured in. By early cleansing, the yeast is preserved longer in a state proper for a perfect fermentation, than by a contrary practice.

For old ale, which is to be long kept, the heat of the fermentation should not exceed 75°, but a longer time is required to complete the fermentation and ensure the future good flavour of the ale.

For porter, the general practice is, to use from 4 to 4½ lbs of hops per barrel for keeping; though what is termed mild or mixing porter, has not more than 3 or 3½ lbs. The heat of fermentation must not exceed 70°, and begin about 60°. If the heat tend to increase much above that pitch in the gyle-tun, the porter should be *cleansed* by means of the *stillions*. At this period of the fermentation, care should be taken that the sweetness of the malt be removed, for which purpose more yeast may be used than with any other beer of the same strength. The quantity is from 3 to 4 lbs. per barrel, rousing the wort in the gyle-tun every 2 hours in the day-time.

When the plan of *cleansing* casks is not employed, the yeast is removed from the surface of the fermenting tun by a skimmer, and the clear beer beneath is then drawn off into the ripening tuns, called *store-vats*, in which it is mixed up with different brewings, to suit the taste of the customers. This transfer must take place whenever the extrication of carbonic acid has nearly ceased; lest the alcohol formed should dissolve some of the floating yeast, acquire thereby a disagreeable taste, and pass partially into the acetous state.

In this process, during the formation of vinous spirit at the expense of the sugar, the albumen and gluten diffused through the beer, being acted upon by the alcohol, become insoluble; one portion of them is buoyed to the top with the carbonic acid gas, to form the frothy yeast, and another portion falls to form the bottom barm. The former consists of the same materials as the wort, with a large proportion of gluten, which forms its active constituent; the latter is a peculiar deposit, consisting of the same gluten, mixed with the various dense impurities of the wort, and may be also used as a ferment, but is cruder than the floating yeast. The amount of yeast is proportional to the activity of the fermentation, or extrication of carbonic acid gas, as also to the heat of the mashing process, and the quantity of starch or flour unaltered by germination. Pale malt affords, usually, more yeast than malt highly kilned. When the yeast becomes excessive, from too violent fermentation, it should be skimmed off from time to time, which will tend to cool the liquor and moderate the intestine changes.

After the beer is let down into the close store-tuns in the cellar, an obscure fermentation goes on for a considerable period in its body, which increases its spirituous strength, and keeps up in it a constant impregnation of carbonic acid gas, so as to render it lively and agreeable to the taste, when it is casked off for sale. It would appear that beer is never stationary in quality while it is contained in the tuns; for the moment when it ceases to improve by the decomposition of its residuary sugar, it begins to degenerate into vinegar. The result may be produced either by the exhaustion of the saccharine or by the fermentative matter. The store cellar should therefore be under ground, free from alternations of temperature, vibrations of carriages, and as cool as possible. In the great London breweries, the fermentation is rendered very complete in the cleansing butts; so that a slow and steady ripening is ensured in the great store tuns. The gyle-tuns are too capacious to permit the fermentation to be finished, with either safety or sufficient dispatch in them.

Beer, in its perfect condition, is an excellent and healthful beverage, combining, in

Digitized by Google

some measure, the virtues of water, of wine, and of food, as it quenches thirst, stimulates, cheers, and strengthens. The vinous portion of it is the alcohol, proceeding from the fermentation of the malt sugar. Its amount, in common strong ale or beer, is about 4 per cent., or four measures of spirits, specific gravity 0·825, in 100 measures of the liquor. The best brown stout porter contains 6 per cent., the strongest ale even 8 per cent., but common beer only one. The nutritive part of the beer is the undecomposed gum-sugar, and the starch-gum not changed into sugar. Its quantity is very variable, according to the original starch of the wort, the length of the fermentation, and the age of the beer.

The main feature of good beer is fine colour and transparency; the production of which is an object of great interest to the brewer. Attempts to clarify it in the cask seldom fail to do it harm. The only thing that can be used with advantage for *fining* foul or muddy beer, is isinglass. For porter, as commonly brewed, it is frequently had recourse to. A pound of good isinglass will make about 12 gallons of *finings*. It is cut into slender shreds, and put into a tub with as much vinegar or hard beer as will cover it, in order that it may swell and dissolve. In proportion as the solution proceeds, more beer must be poured upon it, but it need not be so acidulous as the first, because, when once well softened by the vinegar, it readily dissolves. The mixture should be frequently agitated with a bundle of rods, till it acquires the uniform consistence of thin treacle, when it must be equalised still more by passing through a tammy cloth, or a sieve. It may now be made up with beer to the proper measure of dilution. The quantity generally used is from a pint to a quart per barrel, more or less, according to the foulness of the beer. But before putting it into the butt, it should be diffused through a considerable volume of the beer with a whisk, till a frothy head be raised upon it. It is in this state to be poured into the cask, briskly stirred about; after which the cask must be bunged down for at least 24 hours, when the liqour should be limpid. Sometimes the beer will not be improved by this treatment; but this should be ascertained beforehand, by drawing off some of the beer into a cylindric jar or phial, and adding to it a little of the finings. After shaking and setting down the glass, we shall observe whether the feculencies begin to collect in flocky parcels, which slowly subside; or whether the isinglass falls to the bottom without making any impression upon the beer. This is always the case when the fermentation is incomplete, or a secondary decomposition has begun. Mr. Jackson has accounted for this clarifying effect of isinglass in the following way.

The isinglass, he thinks, is first of all rather diffused mechanically, than chemically dissolved, in the sour beer or vinegar, so that when the finings are put into the foul beer, the gelatinous fibres, being set free in the liqour, attract and unite with the floating feculencies, which before this union were of the same specific gravity with the beer, and therefore could not subside alone; but having now acquired additional weight by the coating of fish-glue, precipitate as a flocculent magma. This is Mr. Jackson's explanation; to which we might add, that if there be the slightest disengagement of carbonic acid gas, it will keep up an obscure locomotion in the particles, which will prevent the said light impurities, either alone or when coated with isinglass, from subsiding. The beer is then properly enough called *stubborn* by the coopers. The true theory probably of the action of isinglass is, that the tannin of the hops combines with the fluid gelatine, and forms a flocculent mass which envelopes the muddy particles of the beer, and carries them to the bottom as it falls, and forms a sediment. When, after the finings are poured in, no proper precipitate ensues, it may be made to appear by the addition of a little decoction of hop.

Mr. Richardson, the author of the well-known brewer's saccharometer, gives the following as the densities of different kinds of beer:—

Beer.	Pounds per Barrel.	Specific Gravity.
Burton ale, 1st sort - - -	40 to 43	1·111 to 1·120
„ 2nd „ - - -	35 to 40	1·097 to 1·111
„ 3rd „ - - -	28 to 33	1·077 to 1·092
Common ale - - - -	25 to 27	1·070 to 1·073
Ditto ditto - - - -	21	1·058
Porter, common sort - - -	18	1·050
„ double - - - -	20	1·055
„ brown stout - - -	23	1·064
„ best brown stout - -	26	1·072
Common small beer - - -	6	1·014
Good table beer - - -	12 to 14	1·033 to 1·039

When *small beer* is brewed after *ale* or *porter*, only one after-mash is to be made; but where this is not done, there may be two mashes, in order to economise malt to the utmost. We may let on the water at 160° or 165°, in any convenient quantity, infuse for an hour or thereabouts, then run it off, and pump into the copper, putting some hops into it, and causing it to boil for an instant, when it may be transferred to the cooler. A second mash or return may be made in the same manner, but at a heat 5° lower; and then disposed of in the boiler with some hops, which may remain in the copper during the night at a scalding heat, and may be discharged into the cooler in the morning. These two returns are to be let down into the under-back immediately before the next brewing, and thence heated in the copper for the next mashing of fresh malt, instead of hot water, commonly called *liquor* in the breweries. But allowance must be made, in the calculation of the worts, for the quantity of fermentable matter in these two returns. The nett aggregate saving is estimated from the gravity of the return taken when cold in the cooler. A slight economy is also made in the extra boiling of the used hops.

It may be remarked that Mr. Richardson somewhat underrates the gravity of porter, which is now seldom under 20 lbs. per barrel. The criterion for transferring from the gyle-tun to the cleansing butts is the attenuation caused by the production of alcohol in the beer: when that has fallen to 10 lbs. or 11 lbs., which it usually does in 48 hours, the cleansing process is commenced. The heat is at this time generally 75°, if it was pitched at 65°; for the heat and the attenuation go hand in hand.

About forty years ago, it was customary for the London brewers of porter to keep immense stocks of it for eighteen months or two years, with the view of improving its quality. The beer was pumped from the cleansing butts into store-vats holding from twenty to twenty-five gyles or brewings of several hundred barrels each. The store-vats had commonly a capacity of 5000 or 6000 barrels; and a few were double, and one was treble, this size. The porter, during its long repose in these vats, became fine, and by obscure fermentation its saccharine mucilage was nearly all converted into vinous liquor, and partly dissipated in carbonic acid. Its hop-bitter was also in a great degree decomposed. *Good hard beer* was the boast of the day. This was sometimes softened by the publican, by the addition of some mild new-brewed beer. Of late years, the taste of the metropolis has undergone such a complete revolution in this respect, that nothing but the mildest porter will now go down. Hence, six weeks is a long period for beer to be kept in London; and much of it is drunk when only a fortnight old. Ale is for the same reason come greatly into vogue; and the two greatest porter houses, Messrs. Barclay, Perkins, and Co., and Truman, Hanbury, and Co., have become extensive and successful brewers of mild ale, to please the changed palate of their customers.

We shall add a few observations upon the brewing of Scotch ale. This beverage is characterised by its pale amber colour and its mild balsamic flavour. The bitterness of the hop is so mellowed with the malt as not to predominate. The ale of Preston Pans is, in fact, the best substitute for wine which barley has hitherto produced. The low temperature at which the Scotch brewer pitches his fermenting tun restricts his labours to the colder months of the year. He does nothing during four of the summer months. He is extremely nice in selecting his malt and hops; the former being made from the best English barley, and the latter being the growth of Farnham or East Kent. The yeast is carefully looked after, and measured into the fermenting tun in the proportion of one gallon to 240 gallons of wort.

Only one mash is made by the Scotch ale brewer, and that pretty strong; but the malt is exhausted by eight or ten successive sprinklings of liquor (hot water) over the goods (malt), which are termed, in the vernacular tongue, *sparges*. These waterings percolate through the malt on the mash-tun bottom, and extract as much of the saccharine matter as may be sufficient for the brewing. By this simple method much higher specific gravities may be obtained than would be practicable by a second mash. With malt, the infusion or saccharine fermentation of the *diastase* is finished with the first mash; and nothing remains but to wash away from the goods the matter which that process has rendered soluble. It will be found on trial that 20 barrels of wort drawn from a certain quantity of malt, by two successive mashings, will not be so rich in fermentable matter as 20 barrels extracted by ten successive sparges of two barrels each. The grains always remain soaked with wort like that just drawn off, and the total residual quantity is three-fourths of a barrel for every quarter of malt. The gravity of this residual wort will on the first plan be equal to that of the second mash; but, on the second plan, it will be equal only to that of the tenth sparge, and will be more attenuated in a very high geometrical ratio. The only serious objection to the sparging system is the loss of time by the successive drainages. A mash-tun with a steam jacket, promises to suit the sparging system well, as it would keep up

Digitized by Google

an uniform temperature in the goods, without requiring them to be sparged with very hot liquor.

The first part of the Scotch process seems of doubtful economy; for the mash liquor is heated so high as 180°. After mashing for about half an hour, or till every particle of the malt is thoroughly drenched, the tun is covered, and the mixture left to infuse about three hours; it is then drained off into the under-back, or preferably into the wort copper.

After this wort is run off, a quantity of liquor (water), at 180° of heat, is sprinkled uniformly over the surface of the malt; being first dashed on a perforated circular board, suspended horizontally over the mash-tun, wherefrom it descends like a shower upon the whole of the goods. The percolating wort is allowed to flow off by three or more small stopcocks round the circumference of the mash-tun, to insure the equal diffusion of the liquor.

The first sparge being run off in the course of twenty minutes, another similar one is affused; and thus in succession till the whole of the drainage, when mixed with the first mash-wort, constitutes the density adapted to the quality of the ale. Thus, the strong worts are prepared, and the malt is exhausted either for table beer, or for a *return*, as pointed out above. The last sparges are made 5° or 6° cooler than the first.

The quantity of hops seldom exceeds four pounds to the quarter of malt. The manner of boiling the worts is the same as that above described; but the conduct of the fermentation is peculiar. The heat is pitched at 50°, and the fermentation continues from a fortnight to three weeks. Were three brewings made in the week, seven or eight working tuns would thus be in constant action; and, as they are usually in one room, and some of them at an *elevation* of temperature of 15°, the apartment must be propitious to fermentation, however low its heat may be at the commencement. No more yeast is used than is indispensable: if a little more be needed, it is made effective by rousing up the tuns twice a day from the bottom.

When the progress of the attenuation becomes so slack as not to exceed half a pound in the day, it is prudent to cleanse, otherwise the top barm might re-enter the body of the beer, and it would become *yeast-bitten*. When the ale is cleansed, the head, which has not been disturbed for some days, is allowed to float on the surface till the whole of the *then* pure ale is drawn off into the casks. This top is regarded as a sufficient preservative against the contact of the atmosphere. The Scotch do not skim their tuns, as the London ale brewers commonly do. The Scotch ale, when so cleansed, does not require to be set upon close stillions. It throws off little or no yeast, because the fermentation was nearly finished in the tun. The strength of the best Scotch ale ranges between 32 and 44 pounds to the barrel; or it has a specific gravity of from 1·088 to 1·122, according to the price at which it is sold. In a good fermentation, seldom more than a fourth of the original gravity of the wort remains at the period of the cleansing. Between one-third and one-fourth is the usual degree of attenuation. Scotch ale soon becomes fine, and is seldom racked for the home market. The following Table will show the progress of fermentation in a brewing of good Scotch ale:—

20	barrels of	mash-worts of	$42\frac{1}{2}$	pounds gravity	= 860·6
20	—	returns	$6\frac{1}{10}$	„ „	= 122
					12) 982·6

pounds weight of extract per quarter of malt = 81

Fermentation:—

March 24, pitched the tun at 51°: yeast 4 gallons.

		Temp.	Gravity.
	25.	52 degrees.	41 pounds.
	28.	56 „	39 „

Dr. Ure was employed to make experiments on the density of worts, and the fermentative changes which they undergo, for the information of a committee of the House of Commons, which sat in July and August, 1830: the following is a short abstract of that part of his evidence which bears upon the present subject: –

"My first object was to clear up the difficulties which, to common apprehension, hung over the matter, from the difference in the scales of the saccharometers in use among the brewers and distillers of England and Scotland. I found that one quarter of good malt would yield to the porter brewer a barrel Imperial measure of wort, at the concentrated specific gravity of 1·234. Now, if the decimal part of this number be multiplied by 360, being the number of pounds weight of water in the barrel, the product will denote the excess, in pounds, of the weight of a barrel of such concentrated wort over that of a barrel of water, and that product is, in the present case, 84·24 pounds.

"Mr. Martineau, jun., of the house of Messrs. Whitbread and Company, and a gentleman connected with another great London brewery, had the kindness to inform me that their average product from a quarter of malt was a barrel of 84 lbs. gravity. It is obvious, therefore, that by taking the mean operation of two such great establishments, I must have arrived very nearly at the truth.

"It ought to be remarked that such a high density of wort as 1·234 is not the result of any direct experiment in the brewery, for infusion of malt is never drawn off so strong; that density is deduced by computation from the quantity and quality of several successive infusions; thus, supposing a first infusion of the quarter of malt to yield a barrel of specific gravity 1·112, a second to yield a barrel at 1·091, and a third a barrel at 1·031, we shall have three barrels at the mean of these three numbers, or one barrel at their sum, equal to 1·234.

"I may here observe that the arithmetical mean or sum is not the true mean or sum of the two specific gravities; but this difference is either not known or disregarded by the brewers. At low densities this difference is inconsiderable, but at high densities it would lead to serious errors. At specific gravity 1·231, wort or syrup contains one-half of its weight of solid pure saccharum, and at 1·1045 it contains one-fourth of its weight; but the brewer's rule, when here applied, gives for the mean specific gravity $1{\cdot}1155 = \frac{1{\cdot}231 + 1{\cdot}000.}{2}$ The contents in solid saccharine matter at that density are however 27¼ per cent., showing the rule to be 2¼ lbs. wrong in excess on 100 lbs., or 9 lbs. per barrel.

"The specific gravity of the solid dry extract of malt-wort is 1·264; it was taken in oil of turpentine, and the result reduced to distilled water as unity. Its specific volume is 0·7911, that is, 10 lbs. of it will occupy the volume of 7·911 lbs. of water. The mean specific gravity, by computation of a solution of that extract in its own weight of water, is 1·1166; but, by experiment, the specific gravity of that solution is 1·216, showing considerable condensation of volume in the act of combination with water.

"The following Table shows the relation between the specific gravities of solutions of malt extract and the per-centage of solid extract they contain: —

Extract of Malt.		Water.	Malt Extract in 100.	Sugar in 100.	Specific gravity.
600	+	600	50·00	47·00	1·2160
600	+	900	40·0	37·00	1·1670
600	+	1200	33·3	31·50	1·1350
600	+	1500	28·57	26·75	1·1130
600	+	1800	25·00	24·00	1·1000

"The extract of malt was evaporated to dryness, at a temperature of about 250° F., without the slightest injury to its quality or any empyreumatic smell. Bate's tables have been constructed on solutions of sugar, and not with solutions of extract of malt, as they agree sufficiently well with the former, but differ materially from the latter. Allen's tables give the account of a certain form of solid saccharine matter extracted from malt, and dried at 175° F., in correspondence to the specific gravity of the solution; but I have found it impossible to make a solid extract from infusions of malt, except at much higher temperatures than 175° F. Indeed, the numbers on Allen's saccharometer scale clearly show that his extract was by no means dry: thus, at 1·100 of gravity he assigns 29·669 per cent. of solid saccharine matter; whereas there is at that density of solid extract only 25 per cent. Again, at 1·135, Allen gives 40 parts per cent. of solid extract, whereas there are only 33⅓ present."

The following Table shows the origin and effect of fermentation in the reduction of gravity, in a number of practical experiments:—

Original Gravity of the Worts.	lbs. per Barrel of Saccharine Matter.	Specific Gravity of the Ale.	lbs. per Barrel of Saccharine Matter.	Attenuation, or Saccharumdecomposed.
1·0950	88·75	1·0500	40·25	0·478
1·0918	85·62	1·0420	38·42	0·552
1·0829	78·125	1·0205	16·87	0·787
1·0862	80·625	1·0236	20·00	0·757
1·0780	73·75	1·0280	24·25	0·698
1·0700	65·00	1·0285	25·00	0·615
1·1002	93·75	1·0400	36·25	0 613
1·1025	95·93	1·0420	38·42	0·600
1·0978	91·56	1·0307	27·00	0·705
1·0956	89·37	1·0358	32·19	0·640
1·1130	105·82	1·0352	31·87	0·661
1·1092	102·187	1·0302	26·75	0·605
1·1171	110·00	1·0400	36·25	0·669
1.1030	96·40	1·0271	23·42	0·757
1·0660	61·25	1·0214	17·80	0·709

The second column here does not represent the solid extract, but the pasty extract obtained as the basis of Mr. Allen's saccharometer, and therefore each of its numbers is somewhat too high. The last column, also, must be in some measure erroneous, on account of the quantity of alcohol dissipated during the process of fermentation. It must be likewise incorrect, because the density due to the saccharine matter will be partly counteracted by the effect of the alcohol present in the fermented liquor. In fact, the attenuation does not correspond to the strength of the wort; being greatest in the third brewing and smallest in the first. The quantity of yeast for the above ale brewings in the Table was, upon an average, one gallon for 108 gallons; but it varied with its quality, and with the state of the weather, which, when warm, permits much less to be used with propriety.

The good quality of the malt, and the right management of the mashing, may be tested by the quantity of saccharine matter contained in the successively drawn worts. With this view, an aliquot portion of each of them should be evaporated by a safety-bath heat to a nearly concrete consistence, and then mixed with twice its volume of strong spirit of wine. The truly saccharine substance will be dissolved, while the starch and other matters will be separated; after which the proportions of each may be determined by filtration and evaporation. Or an equally correct, and much more expeditious, method of arriving at the same result would be, after agitating the viscid extract with the alcohol in a tall glass cylinder, to allow the insoluble fecula to subside, and then to determine the specific gravity of the supernatant liquid by a hydrometer. The additional density which the alcohol has acquired will indicate the quantity of malt sugar which it has received. The following Table, constructed by Dr. Ure, at the request of Henry Warburton, Esq., M.P., chairman of the Molasses Committee of the House of Commons in 1830, will show the brewer the principle of this important inquiry. It exhibits the quantity in grains' weight of sugar requisite to raise the specific gravity of a gallon of spirit of different densities to the gravity of water = 1·000.

Specific Gravity of Spirit.	Grains' Weight of Sugar in the Gallon Imperial.
0·995	980
0·990	1·890
0·985	2·800
0·980	3·710
0·975	4·690
0·970	5·600
0·965	6·650
0·960	7·070
0·955	8·400
0·950	9·310

The immediate purpose of this Table was to show the effect of saccharine matter in disguising the presence or amount of alcohol in the weak feints of the distiller. But a similar Table might easily be constructed, in which, taking a uniform quantity of alcohol of 0·825, for example, the quantity of sugar in any wort-extract would be

Digitized by Google

shown by the increase of specific gravity which the alcohol received from agitation with a certain weight of the wort, inspissated to a nearly solid consistence by a safety-pan made on the principle of Dr. Ure's patent sugar-pan. (See SUGAR.) Thus, the normal quantities being 1000 grains'-measure of alcohol, and 100 grains by weight of inspissated mash-extract, the hydrometer would at once indicate, by help of the Table, first, the quantity per cent. of truly saccharine matter, and next, by subtraction, that of farinaceous matter present in it.

The advance of the arts is gradually assuming a character which will no longer permit any manufacturer to neglect the assistance of science; and those who first take advantage of the power of knowledge will assuredly leave their fellow-labourers behind. From being an uncertain and hazardous operation, brewing must ere long become a fixed and definite principle based upon facts well understood, and capable of perpetual repetition and reproduction at will. To sum up briefly the general details of ale brewing, we may state, that, for most kinds of ale, the attenuation in the first instance should be finished in from 6 to 21 days, according to the strength of the wort; that this attenuation should approach to two-thirds of the whole weight; and that after tunning and cleansing, the ale itself should weigh about one-fourth of the original gravity of the wort. Thus, if the fermenting tun be set with wort of 27lbs., then the attenuation should bring it down to 9 or 10lbs., and the subsequent operations produce an ale weighing from 6 to 7lbs. When these conditions are fulfilled, without much extra trouble or attention, the ale is pretty certain to turn out well, though, in in some localities, ale is never attenuated to more than one-half its original gravity: this kind of ale is, however, very apt to become sour in hot weather and ropy in cold.

Some additional remarks on the brewing of porter, which differs from that of ale both in the nature of the materials used and in the mode of finishing the fermentation, are required. Porter owes its peculiar colour and flavour to burnt saccharine or starchy matter; and this was formerly obtained by burning sugar until it exhaled the odour called by French writers *caramel*. At present, however, nothing but highly-torrefied malt is used; and of this there are several kinds, as brown malt, imperial malt, and black malt; all of which are used by some brewers, whilst others employ only the brown and black, and a few the black alone, for giving colour and flavour. The fermentative quality or saccharine, is, however, the same as that of ale, and is derived from pale or amber malt. As a general rule, the ratio of the colouring and flavouring malts are to the saccharine as about 1 to 5 or 1 to 4; but where black malt only is used, the proportion does not exceed 1 to 10.

The employment of these burnt malts permits a singular act of injustice on the part of the Excise, as regards the drawback on exportation. By the Excise regulations, it is assumed that a quarter of malt will produce four barrels of ale brewed from wort of the sp. gr. 1·054, or 19·4lbs. per barrel; but, although this is hopeless even with pale malt, yet with an admixtnre of brown and black malt the assumption becomes absurd in the extreme. Admitting that, by good management, on the average, four barrels of wort, weighing 20lbs., can be obtained from one quarter of fine pale malt, yet, in the operations of cooling, fermenting, tunning, skimming, and cleansing, a loss of fully 10 per cent. occurs under the most vigilant superintendence; and, taking the great bulk of our metropolitan breweries, it would be nearer the truth to estimate this loss at 12 per cent. In plain words, 100 gallons of wort will not, by any management, produce more than about 88 gallons of saleable beer, though no allowance is made for this by the Excise; and the brewer who has paid duty upon 100 gallons gets a drawback upon but 88. This, however, is the most favourable view of the case; and we solicit attention to the force with which the argument returns in the instance of porter.

If a quarter of pale malt be assumed at 84lbs. of saccharine strength, then such an admixture of brown and black malt as is usually employed by brewers of porter will not give more than about 24lbs.; and as this constitutes at least one-fifth of the whole bulk used in porter brewing, we see that a quarter of such mixed malt can never give more than 70lbs.; that is to say, 80 parts of pale malt, mixed with 20 of brown and black, instead of giving at the rate of 84lbs., as pale malt alone does, would give but 70lbs., or produce a difference between the actual return and that taken for granted by the Excise authorities, of no less than 16·6 per cent.; to which, if we add the loss previously mentioned as arising from fermentation, yeast, &c., and which we have called 12 per cent., a total difference ensues of 28·6 per cent. between the duty paid by the brewer and the drawback allowed by act of parliament. But the grievance does not stop here; for the only return allowed by act of parliament is based upon the malt duty, and nothing whatever is said of the duty on hops. This, however, is at the rate of 19*s.* 7*d.* per cwt.; and since hops yield only about 35 per cent. of their weight of soluble matter, it would require 168lbs. of hops to produce a barrel of fluid or wort weighing 19·4 lbs., or having the requisite parliamentary specific gravity of

Digitized by Google

of 1·054. Upon this barrel, when exported, the drawback is 5*s.*; but, as may easily be seen on calculation, the duty paid by the brewer has been 29*s.* 3*d.* In fact, upon every 168 lbs. of hops consumed by the export brewer, he suffers a dead loss of 24*s.* 3*d.* independently of the waste incidental to his various processes. These things may seem startling; but the whole Board and Staff of the Excise are unable to prove that they are in the least over-estimated. At the same time the intelligent reader will gather that the profits of brewing are not by any means so large as a cursory glance at the subject might warrant: and we say this rather as having reference to schemes now in progress for reducing the price of beer than from its connection with our general arrangements. No doubt the brewing business is at times very remunerative; but a continued high price of the raw materials sometimes proves ruinous to the large brewer, as it must not be forgotten that the capital required is large, and invested in very perishable materials, such as casks and other wooden utensils, the wear and tear upon which is a very large item; nor, again, as we have shown, must a speculator begin by assuming, with the Excise authorities, that a quarter of malt will produce four barrels of beer, for he will be much nearer the truth if he estimates his saleable produce at three barrels. As, however, it forms no part of our present task to enter into the financial statistics of brewing, we return to the object more immediately in view, merely throwing out, *en passant*, the above hints for the benefit of those whom they may concern.

If the analyses of malt and malt-wort are requisite to enable the brewer to perform his operations with safety and success, the analysis of beer is not less indispensable to qualify him for the harassing labour of competition with his neighbours, and for the protection of his interest against Excise confiscation. Although beer may have been brewed of the requisite gravity for justifying a drawback on exportation, yet this is very far indeed from ensuring a return of the malt duty, even to the limited extent awarded by law. The question is, How are the Excise officials to know the real weight of the wort from which the beer was brewed? This may be ascertained by the following method, which should take the place of the present indefinite system:—Having agitated a portion of the ale or beer so as to dissipate its carbonic acid gas, measure out exactly 3600 grains'-measure of it, and pour these into a retort; then distil with great care into a receiver surrounded by ice-cold water about one-third of the whole fluid, or rather more than this if the ale or beer is known to be highly alcoholic. Next weigh the distilled fluid, and then ascertain its specific gravity, from whence, by any of the proper tables of *alcohol* (*which see*), the total quantity of absolute alcohol in the distilled fluid may be known. This alcohol is to be converted by calculation into its equivalent of sugar, at the rate of 171 parts of sugar for every 92 of alcohol found; after which the sugar must be brought into pounds per barrel by the rule before given, which is 52½ lbs. of sugar for every 20 lbs. of gravity. The amount of vinegar is next to be determined by any of the known forms of acidimetry. (See ACETIMETRY.) This vinegar, or acetic acid, must, like the alcohol, be also converted into its representative of sugar, by assigning 171 of sugar to every 102 of anhydrous acetic acid present in the beer, this sugar being, as before, converted into pounds per barrel. To the beer remaining in the retort, sufficient distilled water is then to be added, that the entire bulk of fluid may once more be equal to 3600 grains'-measure; and the temperature of the mixture having fallen to 60° F., its specific gravity must be determined in the usual way, and this reduced to pounds per barrel, by multiplying the excess above 1000 by 360, and dividing the product by 1000. The whole of these weights, added together, gives the original weight of the wort. Thus, for example, we will suppose that 3600 grains of a particular beer have given 1300 grains of a dilute alcohol, of specific gravity 0·9731, and consequently containing about 17¼ per cent. by weight of alcohol; again, that the same quantity of beer, when tested by ammonia, has indicated 30 grains of acetic acid; and lastly, that the spent wash, when filled up with distilled water to its primary bulk, has, at 60°, a specific gravity of 1·016; then the total alcohol would be in 360 grains, or the representative of a barrel, 22¾ grains, and the acetic acid in the same quantity, 3 grains: hence we have the following results:—

	Grs. of sugar.		Brewers' lbs.
Alcohol, 22¾ grains, equal to - -	42·2	or	16·
Acetic acid, 3 grains - - - -	5·	„	1·9
Spent wash, of specific gravity 1·016 -		„	5·76
Total weight - -			23·66

It might be thought that the proper kind of sugar to select in this instance as the representative of alcohol and acetic acid should be grape-sugar, whose atomic weight is 180; but it has been shown by Dr. Ure that the kind of sugar actually employed

Digitized by Google

in the construction of our saccharometer tables must have been cane-sugar, the atom of which is 171; and hence the reason why it must be employed in this calculation.

ALE, PALE OR BITTER; *brewed chiefly for the Indian market and for other tropical countries.*—It is a light beverage, with much aroma, and, in consequence of the regulations regarding the malt duty, is commonly brewed from a wort of specific gravity 1·055 or upwards; for no drawback is allowed by the Excise on the exportation of beer brewed from worts of a lower gravity than 1·054. This impolitic interference with the operations of trade compels the manufacturer of bitter beer to employ wort of a much greater density than he otherwise would do; for beer made from wort of the specific gravity 1·042 is not only better calculated to resist secondary fermentation and the other effects of a hot climate, but is also more pleasant and salubrious to the consumer. Under present circumstances the law expects the brewer of bitter beer to obtain four barrels of marketable beer from every quarter of malt he uses, which is just barely possible when the best malt of a good barley year is employed. With every quarter of such malt 16 lbs. of the best hops are used; so that, if we assume the cost of malt at 60*s.* per quarter, and the best hops at 2*s.* per lb., we shall have, for the prime cost of each barrel of bitter beer—in malt, 15*s.*; in hops, 8*s.*; together, 23*s.*; from which, on exportation, we must deduct the drawback of 5*s.* per barrel allowed by the Excise, which brings the prime cost down to 18*s.* per barrel, exclusive of the expense of manufacture, wear and tear of apparatus, capital invested in barrels, cooperage, &c., which constitute altogether a very formidable outlay. As, however, this ale is sold as high as from 50*s.* to 65*s.* per barrel, there can be no doubt that the bitter ale trade has long been, and still continues, an exceedingly profitable speculation, though somewhat hazardous, from the liability of the article to undergo decomposition ere it finds a market.

The East Indian pale ale, or bitter beer, is now brewed in large quantities for the home market at Burton-on-Trent, London, Glasgow, and Leeds, but differs slightly from that exported, as being less bitter and more spirituous. It is brewed solely from the best and palest malts and the finest and most delicate hop, and much of its success depends on the care taken in selecting the best materials for its composition. It also requires the utmost care and attention at every stage of its progress to preserve the colour, taste, and other properties of this ale in their fulness and purity.

For further description of the brewhouse and its appliances, with the various modes of operations, see the article BREWING.

The English ale-bibbers were a few years since startled by a public report, apparently well authenticated, that the French chemists were largely engaged in preparing immense quantities of that most deadly poison *strychnine* for the purpose of drugging the pale bitter ale, in such great vogue at present in Great Britain and its colonies. The following are a few amongst many reasons which might be quoted, to show the absurdity of this report:—1, Strychnine is an exceedingly costly article; 2, It has a most unpleasant metallic bitter taste; 3, It is a notorious poison, and by its use in any brewery would ruin the reputation of the brewer; 4, It cannot be introduced into ordinary beer brewed with hops, because it is entirely precipitated by infusions of that wholesome fragrant herb. In fact, the quercitannic acid of hops is incompatible with strychnia and all its kindred alkaloids. Hence hopped beer becomes in this respect a sanitary beverage, refusing to take up a particle of strychnia and other noxious drugs of like character. Were the *nux vomica* powder, from which strychnia is extracted, even stealthily thrown into the mash tun, its dangerous principle would be all infallibly thrown down with the grounds in the subsequent boiling with the hops.

The varieties of beer depend either upon the difference of their materials, or from a different management of the brewing processes. With regard to the materials, beers differ in the proportion of their malt, hops, and water, and in the different kinds of malt or other grain. To the class of table or small beers, all those sorts may be referred whose specific gravity does not exceed 1·025, which contain about 5 per cent. of malt extract, or nearly 18 lbs. per barrel. Beers of middling strength may be reckoned those between the density of 1·025 and 1·040, which contain, at the average, 7 per cent., or 25 lbs. per barrel. The latter may be made with 400 quarters of malt to 1500 barrels of beer: stronger beers have a specific gravity of from 1·050 to 1·080, and take from 450 to 750 quarters of malt to the same quantity of beer. The strongest beer found in the market is some of the English and Scotch ales, for which from 18 to 27 quarters of malt are taken for 1500 gallons of beer: good porter requires from 16 to 18 quarters for that quantity. Beers are sometimes made with the addition of other farinaceous matter to the malt; but when the latter constitutes the main portion of the grain, the malting of the other kinds of corn becomes unnecessary, for the diastase of the barley-malt changes the starch into sugar during the mashing operation. Even with entirely raw grain, beer is made in some parts of the Continent, the brewers trusting the conversion of the starch into sugar to the

Digitized by Google

action of the gluten alone, at a low mashing temperature, on the principle of Saussure's and Kirchoff's researches.

The colour of the beer depends upon the colour of the malt and the duration of the boil in the copper. The pale ale is made, as we have stated, from steam- or sun-dried malt and the young shoots of the hop; the deep-yellow ale from a mixture of pale-yellow and brown malt; and the dark-brown beer from well-kilned and partly-carbonised malt, mixed with a good deal of the pale to give body. The longer and more strongly heated the malt has been in the kiln, the less weight of extract, *cæteris paribus*, does it afford. In making the fine mild ales, high temperatures ought to be avoided, and the yeast ought to be skimmed off, or allowed to flow very readily from its top, by means of the cleansing-butt system, so that little ferment being left in it to decompose the rest of the sugar, the sweetness may remain unimpaired. With regard to porter, in certain breweries each of the three kinds of malt employed for it is separately mashed, after which the first and the half of the second wort is boiled along with the whole of the hops, and thence cooled, and set to ferment in the gyle-tun. The third-drawn wort, with the remaining half of the second, is then boiled with the same hops, saved by the drainer, and, after cooling, added to the former in the gyle-tun, when the two must be well roused together.

It is obvious from the preceding development of principles, that all amylaceous and saccharine materials, such as potatoes, beans, turnips, as well as cane and starch syrup, molasses, &c., may be used in brewing beer. When, however, a superior quality of brown beer is desired, malted barley is indispensable, and even with these substitutes a mixture of it is most advantageous. The washed roots of the common carrot, of the red and yellow beet, or of the potato, must be first boiled in water, and then mashed into a pulp. This pulp must be mixed with water in the copper along with wheaten or oatmeal and the proper quantity of hops, then boiled during eight or nine hours. This wort is to be cooled in the usual way, and fermented with the addition of yeast. A much better process is that now practised on a considerable scale at Strasbourg, in making the ale for which that city is celebrated. The mashed potatoes are mixed with from a twentieth to a tenth of their weight of finely-ground barley-malt and some water. The mixture is exposed in a water-bath to a heat of 160° F. for four hours, whereby it passes into a saccharine state, and may then be boiled with hops, cooled, and properly fermented into good beer.

Maize, or Indian corn, has also been employed to make beer; but its malting is somewhat difficult, on account of the rapidity and vigour with which its radicles and plumula sprout forth. The proper mode of causing it to germinate is to cover it a few inches deep with common soil, in a garden or field, and to leave it there till the bed is covered with green shoots of the plant. The corn must be then lifted, washed, and exposed to the kiln.

The Board of Excise, or Inland Revenue, having, a few years ago, with delusive liberality, been permitted by the Legislature to grant leave to use sugar in the place of barley-malt in breweries, an extensive sugar merchant in London hoping, under this pretended boon, to acquire a new and wealthy class of customers, employed Dr. Ure to ascertain by experiment the relative values of malt and sugar for the manufacture of beer. Ten samples of Muscovado sugar, of several qualities, were examined, and were found to vary very slightly in the proportions of alcohol they could furnish by fermentation in a brewer's tun, the average being 12 gallons of proof spirit for 112 lbs. of the sugar; whereas an equal quantity of proof spirit could be obtained from $4\frac{4}{10}$ bushels of malt. One pound of malt yields $\frac{3}{4}$ lb. of extract capable of making as much beer as that weight of sugar. On comparing the actual price of sugar and malt, we shall see how ruinous a business it would be to use sugar instead of malt in a brewery, and hence the delusiveness of the Excise generosity towards the beer trade.

Although the object of the brewer is not the formation of a mere saccharine wort, as we have already shown (and malt contains other substances necessary to the formation of a sound beer), the amount of proof spirit producible from various substances will be some index to their relative value; and it has been found that, with proper management, a quarter of good malt, weighing 42 lbs. per bushel, or 336 lbs. per quarter, will yield 18 gallons of proof spirit; a quarter of barley, weighing 55 lbs. per bushel, or 440 lbs. per quarter, will yield from 18 to 20 gallons. An equal quantity of spirit, say 18 gallons at proof, can be obtained from 175 lbs. of best West India sugar; from 234 lbs. of inferior Jamaica raw sugar; from 275 lbs. of West India molasses; or from 295 lbs of refined or sugar-house molasses. Bauerstock gave the average of sugar 200 lbs., and of honey 226 lbs., as equivalent to a quarter of malt.

Ropiness is a morbid state of beer, which is best remedied, according to Mr. Black, by putting the beer into a vat with a false bottom, and adding, per barrel, 4 or 5

Digitized by Google

pounds of hops, taken away after the first boilings of the worts; and to them may be added about half a pound per barrel of mustard-seed. Rouse the beer as the hops are gradually introduced, and, in some months, the ropiness will be perfectly cured. The beer should be drawn off from below the false bottom.

For theoretical views, see FERMENTATION; and for wort-cooling apparatus, see REFRIGERATOR.

BEER, BAVARIAN. The Germans from time immemorial have been habitually beer drinkers, and have exercised much of their technical and scientific skill in the production of beer of many different kinds, some of which are little known to our nation, while one at least, called Bavarian, possesses excellent qualities, entitling it to the attention of all brewers and consumers of this beverage. The peculiarities in the manufacture of Bavarian beer have recently attracted the attention of the most eminent chemists in Germany, especially of Professor Liebig, and much new light has thereby been thrown upon this curious portion of vegetable chemistry.

The following is a list of the principal beers at present brewed in Germany:—

1. Brown beer of Merseburg; of pure barley malt.
2. „ „ „ and beet-root sugar.
3. „ barley malt, potatoes, and beet-root syrup.
4. „ refined beet-root syrup alone.
5. Covent, or thin beer.
6. Berlin white beer, or the Champagne of the north.
7. Broyhan, a famous Hanoverian beer.
8. Double beer of Grünthal.
9. Bavarian beer: 1. Summer beer; 2. Winter beer.
10. „ Bock-beer.
11. Wheat *Lager*-beer (slowly fermented).
12. White bitter beer of Erlangen.

Considerable interest among men of science, in favour of the Bavarian beer process, has been excited ever since the appearance of "Liebig's Organic Chemistry." In the introduction to this admirable work, he says, "The beers of England and France, and for the most part those of Germany, become gradually sour by contact of air. This defect does not belong to the beers of Bavaria, which may be preserved at pleasure in half-full casks, as well as full ones, without alteration in the air. This precious quality must be ascribed to a peculiar process employed for fermenting the wort, called in German *Untergährung*, or fermentation from below; which has solved one of the finest theoretical problems.

"Wort is proportionally richer in soluble gluten than in sugar. When it is set to ferment by the ordinary process, it evolves a large quantity of yeast, in the state of a thick froth, with bubbles of carbonic acid gas attached to it, whereby it is floated to the surface of the liquid. The phenomenon is easily explained. In the body of the wort, alongside of particles of sugar decomposing, there are particles of gluten being oxidised at the same time, and enveloping, as it were, the former particles, whence the carbonic acid of the sugar and the insoluble ferment from the gluten being simultaneously produced, should mutually adhere. When the metamorphosis of the sugar is completed, there remains still a large quantity of gluten dissolved in the fermented liquor, which gluten, in virtue of its tendency to appropriate oxygen, and to get decomposed, induces also the transformation of the alcohol into acetic acid (vinegar). But were all the matters susceptible of oxidisement as well as this vinegar ferment removed, the beer would thereby lose its faculty of becoming sour. These conditions are duly fulfilled in the process followed in Bavaria.

"In that country the malt-wort is set to ferment in open backs, with an extensive surface, and placed in cool cellars, having an atmospheric temperature not exceeding 8° or 10° C. (46½° or 50° F.) The operation lasts from 3 to 4 weeks; the carbonic acid is disengaged, not in large bubbles that burst on the surface of the liquid, but in very small vesicles, like those of a mineral water, or of a liquor saturated with carbonic acid, when the pressure is removed. The surface of the fermenting wort is always in contact with the oxygen of the atmosphere, as it is hardly covered with froth, and as all the yeast is deposited at the bottom of the back under the form of a very viscid sediment, called in German *Unterhefe*.

"In order to form an exact idea of the difference between the two processes of fermentation, it must be borne in mind that the metamorphosis of gluten, and of azotised bodies in general, is accomplished successively in two principal periods, and that it is in the *first* that the gluten is transformed in the interior of the liquid into an insoluble ferment, and that it separates alongside of the carbonic acid proceeding from the

Digitized by Google

sugar. This separation is the consequence of an absorption of oxygen. It is, however, hardly possible to decide if this oxygen comes from the sugar, from the water, or even from an intestine change of the gluten itself; or, in other words, whether the oxygen combines directly with the gluten, to give it a higher degree of oxidation, or whether it lays hold of its hydrogen to form water.

"This oxidation of the gluten, from whichever cause, and the transformation of the sugar into carbonic acid and alcohol, are two actions so correlated, that by an exclusion of the one, the other is immediately stopped."

The *superficial* ferment (*Oberhefe* in German) which covers the surface of the fermenting works, is gluten oxidised in a state of putrefaction; and the ferment of *deposit* is the gluten oxidised in a state of *érémacausis*.

The surface yeast, or barm, excites in liquids containing sugar and gluten the same alteration which itself is undergoing, whereby the sugar and the gluten suffer a rapid and tumultuous metamorphosis. We may form an exact idea of the different states of these two kinds of yeast by comparing the *superficial* to vegetable matters putrefying at the bottom of a marsh, and the *bottom* yeast to the rotting of wood in a state of *érémacausis*, that is, of slow combustion. The peculiar condition of the elements of the *sediment* ferment causes them to act upon the elements of the sugar in an extremely slow manner, and excites the change into alcohol and carbonic acid, without that of the dissolved gluten.

If to wort at a temperature of from 46½° to 50° F. the top yeast be added, a quiet slow fermentation is produced, but one accompanied with a rising up of the mass, while yeast collects both at the surface and bottom of the backs. If this deposit be removed to make use of it in other operations, it acquires by little and little the characters of the *Unterhefe*, and becomes incapable of exciting the phenomena of the first fermenting period, causing only, at 59° F., those of the second, namely, sedimentary fermentation. It must be carefully observed that the right *Unterhefe* is not the precipitate which falls to the bottom of backs in the ordinary fermentation of beer, but is a matter entirely different. Peculiar pains must be taken to get it genuine, and in a proper condition at the commencement. Hence the brewers of Hesse and Prussia, who wished to make Bavarian beer, found it more to their interest to send for the article to Wurtsburg, or Bamberg, in Bavaria, than to prepare it themselves. When once the due primary fermentation has been established and well regulated in a brewery, abundance of the true *Unterhefe* may be obtained for all future operations.

In a wort made to ferment at a low temperature with deposit only, the presence of the *Unterhefe* is the first condition essential to the metamorphosis of the *saccharum*, but it is not competent to bring about the oxidation of the gluten dissolved in the wort, and its transformation into an insoluble state. This change must be accomplished at the cost of the atmospherical oxygen.

In the tendency of soluble gluten to absorb oxygen, and in the free access of the air, all the conditions necessary for its *érémacausis* are to be found. It is known that the presence of oxygen and soluble gluten are also the conditions of acetification (vinegar making), but they are not the only ones; for this process requires a temperature of a certain elevation for the alcohol to experience this slow combustion. Hence, by excluding that temperature, the combustion (oxidation) of alcohol is obstructed, while the gluten alone combines with the oxygen of the air. This property does not belong to alcohol at a low temperature, so that during the oxidation in this case of the gluten, the alcohol exists alongside of it, in the same condition as the gluten alongside of sulphurous acid in the *muted* wines. In wines not impregnated with the fumes of burning sulphur, the oxygen which would have combined at the same time with the gluten and the alcohol does not seize either of them in wines which have been subjected to *mutism*, but it unites itself to the sulphurous acid to convert it into the sulphuric. The action called *sedimentary* fermentation is therefore merely a simultaneous metamorphosis of putrefaction and slow combustion; the sugar and the *Unterhefe* putrefy, and the soluble gluten gets oxidised, not at the expense of the oxygen of the water and the sugar, but of the oxygen of the air, and the gluten then falls in the insoluble state. The process of Appert for the preservation of provisions is founded upon the same principle as the Bavarian process of fermentation, in which all the putrescible matters are separated by the intervention of the air at a temperature too low for the alcohol to become oxidised. By removing them in this way, the tendency of the beer to grow sour, or to suffer a further change, is prevented. Appert's method consists in placing, in presence of vegetables or meat which we wish to preserve, the oxygen at a high temperature, so as to produce slow combustion, but without putrefaction or even fermentation. By removing the residuary oxygen after the combustion is finished, all the causes of an ulterior change are removed. In the sedimentary fermentation of beer, we remove the matter which *experiences* the com-

Digitized by Google

bustion; whereas, on the contrary, in the method of Appert, we remove that which *produces* it.

The temperature at which fermentation is carried on has a very marked influence upon the quantity of alcohol produced. It is known that the juice of beets set to ferment between 86° and 95° F. does not yield alcohol, and its sugar is replaced by a less oxygenated substance, *mannite*, and lactic acid, resulting from the mucilage. In proportion as the temperature is lowered the mannite fermentation diminishes. As to azotised juices, however, it is hardly possible to define the conditions under which the transformation of the sugar will take place, without being accompanied with another decomposition which modifies its products. The fermentation of beer by *deposit* demonstrates that by the simultaneous action of the oxygen of the air and a low temperature, the metamorphosis of sugar is effected in a complete manner; for the vessels in which the operation is carried on are so disposed that the oxygen of the air may act upon a surface great enough to transform all the gluten into insoluble yeast, and thus to present to the sugar a matter constantly undergoing decomposition. The oxidisement of the dissolved gluten goes on, but that of the alcohol requires a higher temperature, whence it cannot suffer acetification, or conversion into vinegar.

In several states of the German confederation, the favourable influence of a rational process of fermentation upon the quality of the beers has been fully recognised. In the Grand Duchy of Hesse considerable premiums were proposed for the brewing of beer according to the process pursued in Bavaria, which were decreed to those brewers who were able to prove that their product (neither strong nor highly hopped) had kept six months in the casks without becoming at all sour. When the first trials were being made, several thousand barrels were being spoiled, till eventually experience led to the discovery of the true practical conditions which theory had foreseen and prescribed.

Neither the richness in alcohol, nor in hops, nor both combined, can hinder ordinary beer from getting tart. In England, says Liebig, an immense capital is sacrificed to preserve the better sorts of ale and porter from souring, by leaving them for several years in enormous tuns quite full, and very well closed, while their tops are covered with sand. This treatment is identical with that applied to wines to make them deposit the wine-stone. A slight transpiration of air goes on in this case through the pores of the wood; but the quantity of azotised matter contained in the beer is so great, relatively to the proportion of oxygen admitted, that this element cannot act upon the alcohol. And yet the beer thus managed will not keep sweet more than two months in smaller casks, to which air has access. The grand secret of the Munich brewers is to conduct the fermentation of the wort at too low a temperature to permit of the acetification of the alcohol, and to cause all the azotised matters to be completely separated by the intervention of the oxygen of the air, and not by the sacrifice of the sugar. It is only in March and October that the good store beer is begun to be made in Bavaria.

The following Table exhibits the results of the chemical examination of the undermentioned kinds of Beer:—

Name of the Beer.	Quantity in 100 parts by weight.				Analyst.
	Water.	Malt extr.	Alcohol.	Carb. acid.	
Augustine double beer — Munich	88·36	8·0	3·6	0·14	Kaiser.
Salvator beer — do. - - -	87·62	8·0	4·2	0·18	Do.
Bock beer from the Royal Brewery — do.	88·64	7·2	4·0	0·16	Do.
Shenck (pot) beer, from a Bavarian country brewery; a kind small beer.	92·94	4·0	2·9	0·16	Do.
Bock beer, of Brunswick, of the Bavarian kind.	88·50	6·50	5·0	- -	Balhorn.
Lager (store) beer, of Brunswick, of the Bavarian kind.	91·0	5·4	3·50	- -	Otto.
Brunswick sweet small beer -	84·70	14·0	1 30	- -	Do.
Brunswick mum - - -	59·2	39·0	1·80	0·1	Kaiser.

Malting in Munich.—The barley is steeped till the acrospire, embryo, or seed-germ, seems to be quickened, a circumstance denoted by a swelling at that end of the grain which was attached to the foot-stalk, as also when, on pressing a pile between two fingers against the thumb nail, a slight projection of the embryo is perceptible. As

Digitized by Google

long, however, as the seed-germ sticks too firm to the husk, it has not been steeped enough for exposure on the under-ground malt-floor. Nor can deficient steeping be safely made up for afterwards by sprinkling the malt-couch with a watering-can, which is apt to render the malting irregular. The steep-water should be changed repeatedly, according to the degree of foulness and hardness of the barley; first, six hours after immersion, having previously stirred the whole mass several times; afterwards, in winter every 24 hours, but in summer every 12 hours. It loses none of its substance in this way, whatever vulgar prejudice may think to the contrary. After letting off the last water from the stone cistern, the Bavarians leave the barley to drain in it during four or six hours. It is now taken out, and laid on the couch floor in a square heap, eight or ten inches high, and it is turned over, morning and evening, with dexterity, so as to throw the middle portion upon the top and bottom of the new-made couch. When the acrospire has become as long as the grain itself, the malt is carried to the *withering* (*Welkboden*) or drying floor, in the open air, where it is exposed (in dry weather) during from eight to fourteen days, being daily turned over three times with a winnowing shovel. It is next dried on a well-constructed cylinder or flue-heated malt-kiln, at a gentle clear heat, without being browned in the slightest degree, while it turns friable into a fine white meal. Smoked malt is entirely rejected by the best Bavarian brewers. Their malt is dried on a series of wove wire horizontal shelves, placed over each other, up through whose interstices, or perforations, streams of air, heated to only 122° F., rise, from the surfaces of rows of hot sheet-iron pipe-flues, arranged a little way below the shelves. Into these pipes the smoke and burned air of a little furnace on the ground are admitted. The whole is enclosed in a vaulted chamber, from whose top a large wooden pipe issues for conveying away the steam from the drying malt. Each charge of malt may be completely dried on this kiln in the space of from 18 to 24 hours, by a gentle uniform heat, which does not injure the diastase or discolour the farina.

The malt for store beer should be kept three months at least before using it, and be freed by rubbing and sifting from the acrospires before being sent to the mill, where it should be crushed pretty fine. The barley employed is the best *distichon* or common kind, styled *Hordeum vulgare*.

The hops are of the best and freshest growth of Bavaria, called the fine *spalter*, or *saatser Bohemian townhops*, and are twice as dear as the best ordinary hops of the rest of Germany. They are in such esteem as to be exported even into France.

In Munich the malt is moistened slightly 12 or 16 hours before crushing it, with from two to three *Maas** of water for every bushel, the malt being well dried, and several months old. The mash-tun into which the malt is immediately conveyed is, in middle-sized breweries, a round oaken tub, about 4½ feet deep, 10 feet in diameter at bottom and 9 at top, outside measure, containing about 6000 Berlin quarts. Into this tun cold water is admitted late in the evening, to the amount of 25 quarts for each *scheffel*, or 600 quarts for the 26 *scheffels* of the ground malt, which are then shot in and stirred about, and worked well about with the oars and rakes, till a uniform paste is formed without lumps. It is left thus for three or four hours; 3000 quarts of water being put into the copper and made to boil; and 1800 quarts are gradually run down into the mash-tun and worked about in it, producing a mean temperature of 142·5 F. After an hour's interval, during which the copper has been kept full, 1800 additional quarts of water are run into the tun, with suitable mashing. The copper being now emptied of water, the mash-mixture from the tun is transferred to it, and brought quickly to the boiling point, with careful stirring to prevent its settling on the bottom and getting burned, and it is kept at that temperature for half an hour. When the mash rises by the ebullition, it needs no more stirring. This process is called, in Bavaria, boiling the thick mash, *dickmaisch Kochen*. The mash is next returned to the tun, and well worked about in it. A few barrels of a thin mash-wort are kept ready to be put into the copper the moment it is emptied of the thick mash. After a quarter of an hour's repose the portion of liquid filtered through the sieve part of the bottom of the tun into the wort-cistern is put into the copper, thrown back boiling hot into the mash in the tun, which is once more worked thoroughly.

The copper is next cleared out, filled up with water, which is made to boil for the after, or small-beer, brewing. After two hours' settling in the open tun, the worts are drawn off clear.

Into the copper, filled up one foot high with the wort, the hops are introduced, and the mixture is made to boil during a quarter of an hour. This is called *roasting the hops*. The rest of the wort is now put into the copper, and boiled along with the hops during at least an hour or an hour and a half. The mixture is then laded out through the hop-filter into the cooling cistern, where it stands three or four inches deep, and

* A Bavarian *maas* = 1¼ quarts English measure.

Digitized by Google

is exposed upon an extensive surface to natural or artificial currents of cold air, so as to be quickly cooled. For every 20 barrels of *Lagerbier* there are allowed 10 of small beer; so that 30 barrels of wort are made in all.

For the winter or pot beer the worts are brought down to about 59° F. in the cooler, and the beer is to be transferred to the fermenting tuns at from 54·5° to 59° F.; for the summer or *Lagerbier*, the worts must be brought down in the cooler to from 43° to 45½°, and put into the fermenting tuns at from 41° to 43° F.

A few hours beforehand, while the wort is still at the temperature of 63½° F., a quantity of *lobb* must be made, called *Vorstellen* (*fore-setting*) in German, by mixing the proportion of *Unterhefe* (yeast) intended for the whole brewing with a barrel or a barrel and a half of the worts, in a small tub called the *Gähr-tiene*, stirring them well together, so that they may immediately run into fermentation. This *lobb* is in this state to be added to the worts. The *lobb* is known to be ready when it is covered with a white froth from one quarter to one half an inch thick, during which it must be well covered up. The large fermenting tun must in like manner be kept covered, even in the vault. The colder the worts, the more yeast must be used. For the above quantity, at

From 57° to 59° F.	- - - -	6	*Maas of Unterhefe.*
„ 53° to 55°	- - - -	8	„ „
„ 48° to 50°	- - - -	10	„ „
„ 41° to 43°	- - - -	12	„ „

Some recommend that wort for this kind of fermentation (the *Untergährung*) should be set with the yeast at from 48° to 57°; but the general practice at Munich is to set the summer or *Lagerbier* at from 41° to 43° F.

By following the preceding directions, the wort in the tun should, in the course of from 12 to 24 hours, exhibit a white froth round the rim, and even a slight whiteness in the middle. After another 12 to 24 hours, the froth should appear in curls; and, in a third like period, these curls should be changed into a still higher frothy brownish mass. In from 24 to 48 hours more, the barm should have fallen down in portions through the beer, so as to allow it to be seen in certain points. In this case it may be turned over into the smaller ripening tuns in the course of other five or six days. But when the worts have been set to ferment at from 41° to 43° F., they require from eight to nine days. The beer is transferred, after being freed from the top yeast by a skimmer, by means of the stopcock near the bottom of the large tun. It is either first run into an intermediate vessel, in order that the top and bottom portions may be well mixed, or into each of the *Lager* casks, in a numbered series, like quantities of the top and bottom portions are introduced. In the ripening cellars the temperature cannot be too low. The best keeping beer can never be brewed unless the temperature of the worts at setting, and of course the fermenting vault, be as low as 50° F. In Bavaria, where this manufacture is carried on under government inspectors, a brewing period is prescribed by law, which is, for the under fermenting *Lagerbier*, from Michaelmas (29th September) to St. George (23rd April). From the latter to the former period the ordinary top-barm beer alone is to be made. The ripening casks must not be quite full, and they are to be closed merely with a loose bung, in order to allow of the working over of the ferment. But should the fermentation appear too languid, after six or eight days, a little briskly fermenting *Lagerbier* may be introduced. The *store Lagerbier* tuns are not to be quite filled, so as to prevent all the yeasty particles from being discharged in the ripening fermentation; but the *pot Lagerbier* tuns must be made quite full, as this beverage is intended for speedy sale within a few weeks of its being made.

As soon as the summer-beer vaults are charged with their ripening casks and with ice-cold air, they are closed air-tight with triple doors, having small intervals between, so that one may be entered and shut again before the next is opened. These vaults are sometimes made in ranges radiating from a centre, and at others in rooms set off at right angles to a main gallery, so that in either case, when the external opening is well secured with triple air-tight doors, it may be entered at any time, in order to inspect the interior without the admission of warm air to the beer-barrels. The wooden bungs for loosely stopping them must be coated with the proper pitch, to prevent the possibility of their imparting any acetous ferment.

Their government has taken great pains to improve this national beverage, by encouraging the growth of the best qualities of hops and barley. The vaults in which the beer is fermented, ripened, and kept, are all under ground, and mostly in stony excavations called *Felsenkeller*, or rock-cellars. The beer is divided into two sorts, called *summer* and *winter*. The latter is light, and, being intended for immediate retail in tankards, is termed *Schankbier*. The other, or the *Lagerbier*, very sensibly increases

Digitized by Google

in vinous strength in proportion as it decreases in sweetness, by the judicious management of the *Nachgährung*, or fermentation in the casks. In several parts of Germany a keeping quality is communicated to beers by burning sulphur in the casks before filling them, or by the introduction of sulphite of lime; but the flavour thus imparted is disliked in Munich, Bayreuth, Regensburg, Nürnberg, Hof, and the other chief towns of Bavaria, instead of which a preservative virtue is sought for in an aromatic mineral, or Tyrol *pitch*, with which the inside of the casks are carefully coated, and in which the ripe beer is kept and exported. In December and January, after the casks are charged with the summer or store beer, the double doors of the cellars are closed, and lumps of ice are piled up against them, to prevent all access of warm air. The cellar is not opened till next August, in order to take out the beer for consumption. In these circumstances the beer becomes transparent like champagne wine; and, since but little carbonic acid gas has been disengaged, little or none of the additionally generated alcohol is lost by evaporation.

The winter or shank (pot) beer is brewed in the months of October, November, March, and April; but the summer or store-beer in December, January, and February, or the period of the coldest weather. For the former beer, the hopped worts are cooled down only to from 51° to 55°, but for the latter to from 41° to 42½° F. The winter beer is also a little weaker than the summer beer, being intended to be sooner consumed; since four bushels* (Berlin measure) of fine, dry, sifted malt, of large heavy *Hordeum vulgare distichon*, affords seven *Eimers* of winter beer, but not more than from five and a half to six of summer beer.† At the second infusion of the worts small beer is obtained to the amount of 20 quarts for the above quantity of malt. For the above quantity of winter beer, 6 lbs. of middling hops are reckoned sufficient; but for the summer beer, from 7 to 8 lbs. of the finest hops. The winter beer may be sent out to the publicans in barrels five days after the fermentation has been completed in the tuns, and, though not quite clear, it will become so in the course of six days; yet they generally do not serve it out in pots for two or three weeks; but the summer beer must be perfectly bright and still before it is racked off into casks for sale.

Bock Beer of Bavaria. — This is a favourite double-strong beverage of the best *lager* description, which is so named from causing its consumers to prance and tumble about like a buck or a goat; — for the German word *Bock* has both these meanings. It is merely a beer having a specific gravity one-third greater, and is therefore made with a third greater proportion of malt, but with the same proportion of hops, and flavoured with a few coriander seeds. It has a somewhat darker colour than the general *Lagerbier*, occasionally brownish, tastes less bitter on account of the predominating malt, and is somewhat aromatic. It is an eminently intoxicating beverage. It is brewed in December and January, and takes a long time to ferment and ripen; but still it contains too large a quantity of unchanged saccharine matter and *dextrine* for its hops, so that it tastes too luscious for habitual topers, and is drunk only from the beginning of May till the end of July, when the fashion and appetite for it are over for the year.

Zimmermann assumes the merit of having introduced Carrageen moss as a clarifier into the beer manufacture. He says that 1 ounce of it is sufficient for 25 gallons of beer; and that it operates, not only in the act of boiling with the hops, but in that of cooling, as also in the squares and backs before the fermentation has begun. Whenever this change, however, takes place, the commixture throws up the gluten and moss to the surface of the liquid in a black scum, which is to be skimmed off, so that the proper yeast may not be soiled with it. It occasions the separation of much of the vegetable slime, or mucilage, called by the German brewers *Pech* (pitch).

On the Clarifying or Clearing of Beers.—Clarifiers act either chemically,—by being soluble in the beer, and by forming an insoluble compound with a vegetable gluten, and other viscid vegetable extracts; gelatine and albumen, under one shape or other, have been most used; the former for beer, the latter, as white of egg, for wine, — or mechanically, by being diffused in fine particles through the turbid liquor, and, in their precipitation carrying down with them the floating vegetable matters. To this class belong sand, bone-black (in some measure, but not entirely), and other such articles. The latter means are very imperfect, and can take down only such matters as exist already in an insoluble state; of the former class, milk, blood, glue, calves'-feet jelly, hartshorn shavings, and isinglass, have been chiefly recommended. Calves'-feet jelly is much used in many parts of Germany, where veal forms so common a kind of butcher-meat; but in summer it is apt to acquire a putrid taint, and to impart the same to the beer. In these islands, isinglass swollen and partly dissolved in vinegar,

* An English quarter of grain is equal to 5 bushels (*schcffel*) and nearly one-third Prussian measure.
† 1 Eimer Prussian = 15¼ English Imperial gallons; 1 Munich *schcffel* is equal to 4 Berlin *schcffels*; 1 Lib. Munich = 1·235 *Eng. lbs. Avoird.*; 1 Lib. Berlin = 1·031 *lbs. Avoird.*

Digitized by Google

or sour beer, is almost the sole clarifier, called finings, employed. It is costly, when the best article is used; but an inferior kind of isinglass is imported for the brewers.

The solvent or medium through or with which it is administered is eminently injudicious, as it never fails to infect the beer with an acetous ferment. In Germany their tart wine has been used hitherto for dissolving the isinglass; and this has also the same bad property. Mr. Zimmermann professes to have discovered an unexceptionable solvent in tartaric acid, one pound of which dissolved in 24 quarts of water is capable of dissolving two pounds of ordinary isinglass; forming finings which may be afterwards diluted with pure water at pleasure. Such isinglass imported from Petersburg into Berlin costs there only 3*s*. per lb. These finings are best added, as already mentioned, to the worts prior to fermentation, as soon as they are let into the setting-back, or tun, immediately after adding the yeast to it. They are best administered by mixing them in a small tub with thrice their volume of wort, raising the mixture into a froth with a whisk (*twig-besom* in German), and then stirring it into the worts. The clarification becomes manifest in the course of a few hours, and when the fermentation is completed, the beer will be as brilliant as can be wished; the test of which with the German topers is when they can read a newspaper while a tall glass beaker of beer is placed between the paper and the candle. One quart of finings of the above strength will be generally found adequate to the clearing of 100 gallons of well-brewed lager-beer, though it will be surer to use double that proportion of finings. The Carrageen moss, as finings, is to be cut in fine shreds, thrown into the boiling thin wort, when the flocks begin to separate, and before adding the hops; after which the boiling is continued for an hour and a half or two hours, as need be. The clarifying with this kind of finings takes place in the cooler, so that a limpid wort may be drawn off into the fermenting back.

Berlin White or Pale Beer (*Weiss-bier*).—This is the truly national beverage of Prussia Proper. It is brewed from 1 part of barley malt and 5 parts of wheat malt, mingled, moistened, and coarsely crushed between rollers. This mixture is worked up first with water at 95° F., in the proportion of 30 quarts per *scheffel* of the malt, to which pasty mixture 70 quarts of boiling water are forthwith added, and the whole is mashed in the tun. After it has been left here a little to settle, a portion of the thin liquor is drawn off by the tap, transferred to the copper, and then for each bushel of malt there is added to it a decoction of half a pound of *Altmark* hops separately prepared. This hopped wort, after half an hour's boiling, is turned back with the hops into the mash-tun, of which the temperature should now be 162½° F., but not more. In half an hour the wort is to be drawn off from the grains, and pumped into the cooler. The grains are afterwards mashed with from 40 to 50 quarts of boiling water per *scheffel* of malt, and this infusion is drawn off and added to the former worts. The whole mixture is set at 66° F., with a due proportion of top yeast or ordinary barm, and very moderately fermented.

Potato Beer.—The potatoes being well washed are to be rubbed down to a pulp by such a grating cylinder machine as is represented in *fig.* 157 (p. 290), where *a* is the hopper for receiving the roots (whether potato or beet, as in the French sugar factories); *b* is the crushing and grinding drum; *c*, the handle for turning the spur-wheel *d*, which drives the pinion *e*, and the fly-wheel *f*; *g*, *h*, is the frame. The dotted lines above *e* are the colander through which the pulp passes. For every *scheffel* of potatoes 80 quarts of water are to be put with them into the copper, and made to boil.

Crushed malt, to the amount of 12 *scheffels*, is to be well worked about in the mash-tun with 360 quarts, or 90 gallons (English), of cold water, to a thick pap, and then 840 additional quarts, or about 6 barrels (English), of cold water are to be successively introduced with constant stirring, and left to stand an hour at rest.

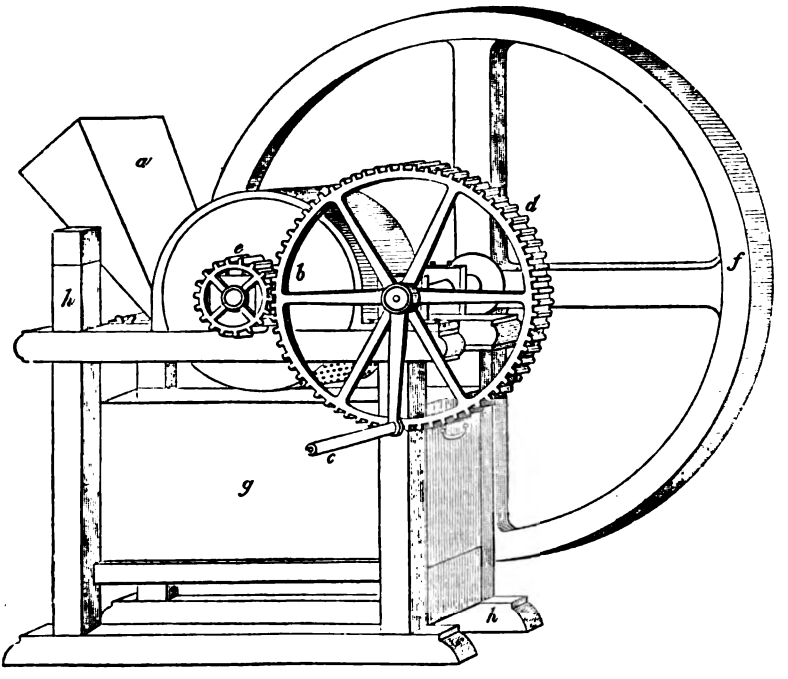
The potatoes having been meanwhile boiled to a fine starch paste, the whole malt-mash, thin and thick, is to be speedily laded into the copper, and the mixture in it is to be well stirred for an hour, taking care to keep the temperature at from 144° to 156° F. all the time, in order that the *diastase* of the malt may convert the starch present in the two substances into sugar and dextrine. This transformation is made manifest by the white pasty liquid becoming transparent and thin. Whenever this happens the fire is to be raised, to make the mash boil, and to keep it at this heat for 10 minutes. The fire is then withdrawn, the contents of the copper are to be transferred into the mash, worked well there, and left to settle for half an hour; during which time the copper is to be washed out, and quickly charged once more with boiling water.

The clear wort is to be drawn off from the tun, as usual, and boiled as soon as possible with the due proportion of hops; and the boiling water may be added in any desired quantity to the drained mash, for the second mashing. Wort made in this way is said to have no flavour whatever of the potato, and to clarify more easily

Digitized by Google

than malt-wort, from its containing a smaller proportion of gluten relatively to that of saccharum.

157



A *scheffel* of good mealy potatoes affords from 26 to 27½ lbs. of thick well-boiled syrup, of the density of 36° Baumé (see AREOMETER); and 26 lbs. of such syrup are equivalent to a *scheffel* of malt in saccharine strength. Zimmermann thinks beer so brewed from potatoes quite equal, at least, if not superior, to pure malt beer, both in appearance and quality.

Fig. 158 is the stopcock used in Bavaria for bottling beer.

The following analyses of German beers are by Leo:—

	Lichtenhain.	Upper Weimar.	Ilmenau.	Jena.	Double Jena.
Alcohol - -	3·168	2·567	3·096	3·018	2·080
Albumen - -	0·048	0·020	0·079	0·045	0·028
Extract - - -	4·485	7·316	7·072	6·144	7·153
Water - - -	92·299	90·097	89·753	90·793	90·739
	100·000	100·000	100·000	100·000	100·000

Under the term extract, in these analyses, is meant a mixture of starch, sugar, dextrine, lactic acid, various salts, certain extractive and aromatic parts of the hop, gluten, and fatty matter.

The quantity of beer and ale *exported* from the United Kingdom amounted in 1850 to 182,480 barrels, and in 1851 to 191,639; the declared value being respectively 558,794*l.*; and 577,874*l.* and in 1856 to 410,412 barrels.

In 1864 we exported from the United Kingdom, as follows:—

Countries to which sent.	Barrels.	Declared real value.

BEES' WAX. The solid matter forming the cells of the honey-comb, secreted according to Huber, by an organ situated in the abdomen of the bee. See WAX.

BEETLE. A name given to a large wooden hammer, usually with two handles, with which wedges, stakes, and the like, are driven.

BEETLE. A name usually given to the insects of the Coleopterous order, especially to those of a dark colour. The species of Coleopterous insects known amount to nearly 40,000. The cantharides are used medicinally. The larva of *Cerambyx heros* was regarded by the Romans as a delicacy. The American Indians eat the larva of *Calandra palmarum*. The name is applied to the annoying insects which infest the kitchens of houses in large towns; they are the *blatta* or cockroach, and belong to the *Orthopterous order*.

BEETLE'S WINGS. The elytra or wing cases of the more brilliantly coloured beetles. (*Coleoptera.*) These are used in making head-dresses for ladies, and for decorating muslins, scarfs, and ball dresses. In Brazil especially, those wings are used for ornaments, and much art is bestowed in their production. Since the Exhibition of 1862, when Brazil exhibited a large collection of the beetle's wing ornaments, a considerable number have been imported.

BEET ROOT. (*Betterave*, Fr.; *rothe Rübe*, Germ.) The large fleshy root of the *beet*, a plant of the genus *Beta*. There are two distinct species cultivated, each containing several varieties. One called *Hortensis*, producing succulent leaves only; the other, the *Vulgaris*, distinguished by its long fleshy root. The variety of the *Vulgaris*, known as the *red beet*, is much cultivated in our gardens, and used as a vegetable. The *white beet* is in much repute in Belgium and France for the manufacture of sugar. See SUGAR.

The common *field beet*, for cattle, which has been long known in Germany, was introduced into England at the latter end of the last century; and its introduction is generally attributed to the late Dr. Lettsom, a physician of great repute, and one of the Society of Friends. The German name is *mangold wurzel*, or mangold root, but is commonly pronounced *mangel wurzel*, which means scarcity root; and, by a strange translation, it is called in French *racine d'abondance*, or root of plenty, as well as *racine de disette*, or root of scarcity. The name *field beet* is much more appropriate. —*Penny Cyclopædia.*

The analyses of Way and Ogston give the following Composition for two Varieties of the Beet Root, and the Analysis of Griepenkerl for another.

Substances contained.	Yellow Globe Mangold Wurzel.		Long Red Mangold Wurzel.		Red Beet.
	Root.	Leaves.	Root.	Leaves.	Root.
Potassa	25·54	8·34	21·68	27·90	51·10

BELLADONA. (*Belledame*, Fr.) The *Atropa Belladona*, or deadly nightshade.
BELL METAL, an alloy of copper and tin. See BRONZE and COPPER.
BELL-METAL ORE. Sulphide of Tin. (*Étain sulphuré*, Haüy; *Zinnkies*, Hausmann.)
The composition of the ordinary variety of this ore is,

Copper - - - - - -	30·0
Iron - - - - - -	12·0
Tin - - - - - -	26·5
Sulphur - - - - -	30·5
	99·0

It was found in many of the Cornish mines, and especially at Carn Brea, but is now rare.
BELLOWS. See METALLURGY.
BELLS. Church bells are said to have been originated in Italy; but bells were certainly cast at a very early period in the East. They were evidently used by the ancient Egyptians, and at a very early date amongst the Chinese. All the more celebrated bells are manufactured of bronze, or bell-metal (these alloys are described under their respective heads).
The following are the weights of a few of the largest bells:—

	lbs.
The great bell of Moscow - - -	443,772
The bell of St. Ivan - - - -	127,836
Another bell in the same city - - -	39,827
Ditto ditto, cast in 1819 - -	112,000
The bell in the cathedral, Paris - -	38,800
Ditto ditto Vienna - -	39,648
The bell in the church at Erfurt - -	30,800
Great Tom of Oxford - - - -	17,000
Ditto Lincoln - - - -	9,894
The bell of St. Paul's, London - -	8,400

The Big Ben of the New Houses of Parliament having proved a failure, evidently from defective casting, the broken fragments of the metal presenting great inequalities, and exhibiting a very porous structure, requires no special notice: of the bell which is to succeed it, we know as yet nothing. Mr. Dennison, to whom Government intrusted the construction of the bell, makes the following remarks on the form of bells in his lecture at the Royal Institution:—
"Now, from these and other experiments, I have come to the conclusion that bells of the common and well-known shape, with a thick lip or sound bow, are the most effective known instruments for producing a loud and musical sound, such as you want when you erect a large public clock, or put up a peal of church bells. And I confess, also, that after trying, at Messrs. Warners', a number of experiments with bells of the usual *general* form, but with various deviation in the details, I am equally satisfied that there is nothing to be gained by deviating materially from the established proportions of the best old bells. And I think it is some confirmation of my views to tell you that Professor Wheatstone, having been commissioned by the Board of Works with Sir C. Barry, on his own suggestion, to collect information at the late Paris Exhibition respecting the most esteemed chimes in France and Belgium, and whether there are in those countries makers acquainted with the traditions of the art, or who have applied the discoveries of science to the improvement of bells, *or to efficient substitutes for them*, has come back with the conclusion that no such efficient substitutes have been discovered; nor is there any known improvement on the established mode and materials for casting them. Sir C. Barry and he, indeed, seem to have been rather impressed with the merits of the cast-steel bells, which you have seen noticed in the newspapers. I have not heard them myself, but I have heard such condemnation of their harshness of sound from other persons, of probably more experience in such matters, that I do not the least believe in their being received generally as an efficient (though they may be a cheap) substitute for the more expensive compound of copper and tin; and, on the whole, that seems to be Professor Wheatstone's opinion also."
In 1864, we *exported* of BELLS and BELL METAL:—

BENGAL STRIPES. Ginghams; a kind of cotton cloth woven with coloured stripes, so called from the cottons which we formerly imported from Bengal.

BEN NUTS. (*Noix de ben*, Fr.; *Salbnusse*, Germ.) The tree which furnishes these nuts is the *Guilandina moringa* of Linnæus, a native of India, Ceylon, Arabia, and Egypt.

BEN OIL. The oil of ben, which may be obtained from the decorticated nuts, is said to be far less liable than other oils to become rancid, and hence it is much used by watchmakers. At a low temperature, the oil of ben separates into two parts—one solid and one fluid; the latter only is used for watch-work. At one time oil of ben was employed as a base for the enfleurage process of making perfumed oils from flowers in the south of France, brought thence from the Levant, but from some unknown reason it has long since ceased to be imported, and oil of ben is now a very rare article of commerce. An attempt has been made in Jamaica, by Mr. Kemble, to raise the moringa for the sake of this oil, but the samples there produced remained a perfectly solid fat in England throughout the whole year.—S. P.

BENZIDINE. ($C^{24}H^{12}N^2$) An alkali, discovered by Zinin, in acting with reducing agents on arzobenzide and azoxibenzide.—C. G. W.

BENZOIN, or BENJAMIN. (*Benjoin*, Fr.; *Benzöe*, Germ.) A species of resin, used chiefly in perfumery; improperly called a gum, since it is quite insoluble in water. It is extracted by incision from the trunk and branches of the *Styrax benzoin*, or *Lithocarpus benzoin*, which grows in Java, Sumatra, Santa Fé, and in the kingdom of Siam. The plant belongs to the *Decandria monogynia* of Linnæus and the natural family of the *Ebenaceæ*. The benzoin flows in small quantities spontaneously from the trees; but it is collected by making incisions in the stem, just below where the branches are given off, as soon as the tree has attained an age of five or six years. These incisions are repeated each year for about twelve years, when the tree becomes exhausted. The resin flows out as a white fluid. It hardens readily in the air, and comes to us in brittle masses, whose fracture presents a mixture of red, brown, and white grains of various sizes, which, when white, and of a certain shape, have been called *amygdaloid*, from their resemblance to almonds The *benzoe in sortis* is very impure, containing portions of wood and bark.

The fracture of benzoin is conchoidal, and its lustre greasy; its specific gravity varies from 1·063 to 1·092. It has an agreeable smell, somewhat like vanilla, which is most manifest when it is ground. It enters into fusion at a gentle heat, and then exhales a white smoke, which may be condensed into the acicular crystals of benzoic acid, of which it contains 18 parts in the hundred. Ether does not dissolve benzoin completely. The fat and volatile oils dissolve very little of it.

Unverdorben has found in benzoin, besides benzoic acid and a little volatile oil, no less than three different kinds of resin, none of which has, however, been turned, as yet, to any use in the arts.

Benzoin is principally used in perfumery; it enters into a number of preparations, among which may be mentioned fumigating pastilles, fumigating cloves (called also nails), *poudre à la maréchale*, &c. The alcoholic tincture, mixed with 20 parts of rose-water, forms the cosmetic *virginal* milk. Benzoin enters also into the composition of certain varnishes employed for snuff-boxes and walking-sticks, in order to give these objects an agreeable smell when they become heated in the hand. It is added to the spirituous solution of isinglass, with which court-plaster is made.

BENZOIC ACID. ($C^{14}H^5O^3$) This acid may be obtained by placing benzoin powdered, with sand, in an evaporating basin, and above it a paper cap; on applying heat carefully to the sand, acid vapours arise from the resin, and they are deposited in the form of fine light crystals with the paper cap. Stolze recommends the following process for extracting the acid:—The resin is to be dissolved in three parts of alcohol, the solution is to be introduced into a retort, and a solution of carbonate of soda dissolved in dilute alcohol is to be gradually added to it, till the free acid be neutralised; and then a bulk of water equal to double the weight of the benzoin is to be poured in. The alcohol being drawn off by distillation, the remaining liquor contains the acid, and the resin floating upon it may be skimmed off and washed, when its weight will be found to amount to about 80 per cent. of the raw material.

BENZOLE. *Syn.* Benzine, benzene, benzol, hydruret of phenyle ($C^{12}H^6$). A compound of carbon and hydrogen discovered by Faraday in the products of the destructive distillation of whale oil. The more volatile portion of coal naphtha has been shown by Mansfield to consist chiefly of this substance. It is produced in a great number of reactions in which organic bodies are exposed to high temperatures. It may at once be obtained in a state of purity by distilling benzoic acid with excess of quicklime. The lime acts by removing two equivalents of carbonic acid from the benzoic acid. The method of obtaining benzole from coal naphtha will be found fully described under the head of

Digitized by Google

NAPHTHA COAL. Benzole is also contained in considerable quantity in bone oil; but it is accompanied by peculiar nitrogenised volatile fluids, which are difficult of removal. The latter, owing to their powerful and fetid odour, greatly injure the quality of the bone-oil benzole. Benzole is an exceedingly volatile fluid, boiling at ordinary pressures at 187° F. Its density is 0·850. Owing to the levity of benzole being regarded by manufacturers as a proof of its purity, it is not uncommon to find it adulterated with the naphtha from the Torbanehill mineral, or Boghead coal, which has a density as low as 0·750. Any benzole having a lower density than 0·850 is impure. Benzole is excessively inflammable, and its vapour mixed with air is explosive. Numerous lives have been lost owing to these properties, among them that of Mr. Mansfield, to whom we are indebted for an excellent investigation on coal naphtha. Benzole is greatly used in commerce, owing to its valuable solvent properties. It dissolves caoutchouc and gutta percha readily, and, on evaporation, leaves them in a state well adapted for waterproofing and many other purposes. Its power of dissolving fatty, oily, and other greasy matters, has caused it to become an article of commerce under the name of benzoline. It readily extracts grease even from the most delicate fabrics, and, as it soon, on exposure to the air, evaporates totally away, no odour remains to betray the fact of its having been used. It dissolves readily in very strong nitric acid, and, on the addition of water, it is precipitated as a heavy oil, having the composition $C^{12}H^5NO^4$. The latter compound is nitrobenzole; it is regarded as benzole in which one equivalent of hydrogen is replaced by hyponitric acid. Nitrobenzole, in a state of tolerable purity, is a pale-yellow oil, having a sweetish taste, and an odour greatly resembling bitter almonds. Owing to its comparative cheapness, it is employed in perfumery. Nitrobenzole can be prepared with nitric acid of moderate strength, such as is ordinarily obtained in commerce; but it then become necessary to distil the acid and the hydrocarbon together several times. The product so obtained is darker in colour, and in other respects inferior to that obtained with highly concentrated acid. By treatment with acetate of protoxide of iron, nitrobenzole becomes transformed into aniline. This change may be effected, but far less conveniently, by means of sulphide of ammonium. Benzole is extremely valuable in many operations of manufacturing chemistry. It dissolves several alkaloids, and, on evaporation, leaves them in a state of purity. It dissolves quinine, but not cinchonine, and may therefore be employed as a means of separation. Morphia and strychnine are also dissolved by it, but not in great quantity. To obtain many natural alkaloids existing in plants, it is merely necessary to digest the dry extract with caustic potash and then with benzole. The latter is to be decanted, and then distilled off on a water-bath. The alkaloid will be left behind in a state well adapted for crystallisation or other means of purification. Benzole is becoming much used as a solvent in researches in organic chemistry. Many substances, such as chrysene and bichloride of naphthaline, crystallise better from benzole than from any other solvent.

Benzole may be employed in many ways for illuminating purposes. It is so easily inflamed that great care is necessary in using it. It does not require a wick to enable it to burn. If poured, even on an uninflammable surface and a light be applied, it takes fire like a train of gunpowder, and burns with a brilliant flame, emitting dense clouds of smoke, which, soon condensing into soot, presently fall in a shower of blacks. Even on the surface of water it burns as freely as anywhere else. If a drachm or two be poured on water contained in a pan, and a pellet of potassium be thrown in, the benzole inflames, and rises in a column of flame of considerable height. A method of destroying enemies' shipping has been founded on this principle. In consequence of the smoky nature of the flame of benzole (caused by the comparatively larger percentage of carbon), it is often convenient to burn a mixture of one volume of benzole and two volumes of alcohol. A stream of air driven through benzole becomes so inflammable as to serve for the purposes of illumination. For this mode of using the hydrocarbon, it should be kept slightly warm to assist its vaporisation. A machine on this principle, of American invention, has been employed to illuminate houses. The air is driven through the benzole by a very simple contrivance, the motive power being a descending weight.

When quite pure, benzole freezes at 32° to a beautiful snow white substance, resembling camphor. The mass retains the solid form until a temperature of 40° or 41° is reached. This property of solidifying under the influence of cold may be made use of to produce pure benzole from the more volatile portion of coal naphtha. To obtain it perfectly pure, it should be frozen at least three times, the portion not solidifying being removed by filtration through calico. The unfrozen portion contains hydrocarbons, homologous with olefiant gas.

Benzole dissolves free iodine and bromine, and has even been used in analysis to separate them from kelp and other substances containing them. They must of course be set free before acting with the hydrocarbon. The presence of benzole in mixtures

Digitized by Google

may easily be demonstrated, even when present in very small quantity, by converting it into aniline, and obtaining the characteristic reaction with chloride of lime. For this purpose the mixture is to be dissolved in concentrated nitric acid and the nitro-benzole precipitated by water. The fluid is then agitated with ether, which dissolves the nitrocompound. The ethereal solution is mixed with an equal bulk of alcohol and hydrochloric acid: a little granulated zinc being added, hydrogen is evolved, and, by acting in a nascent state on the nitro-compound, reduces it to the state of aniline. The base is then to be separated by an excess of potash, and the alkaline fluid is shaken with ether to dissolve the base. The ethereal fluid being evaporated, leaves the aniline. On adding water and then a few drops of solution of chloride of lime, the purple colour indicative of aniline is immediately produced. (*Hofmann.*) The writer of this article has by this process detected minute traces of benzole in mixtures consisting almost entirely of homologues of olefiant gas.—C. G. W.

BERGAMOT. (*Bergamotte*, Fr.) The *Citrus bergamia*, a citron cultivated in the centre and south of Europe. By distillation from the rind of the fruit is obtained the well-known essence of bergamot. See OILS, ESSENTIAL.

The ottoes, or essential oils, from fruits such as the bergamot, the lemon, and the orange may all be procured by distillation, but these products thus procured are not valued by the manufacturing perfumer so much as when they are obtained by rasping the peel of the fruit and collecting the essence thus disengaged, finally filtering. The rasps employed for this purpose are hollow cones filled with spikes, in which the fruit is dexterously revolved by hand. All essences that are distilled are modified in their composition by the presence of the watery vapour and high temperature.—S. P.

BERGAMOT. A coarse tapestry, said to have been invented at Bergamo, in Italy, made of ox and goats' hair, with cotton or hemp.

BERLIN BLUE. A fine variety of the Prussian blue (*which see*).

BERRY. The term is commonly applied, not only to small fruit, but in some cases to seeds. The following is Professor Lindley's definition of a berry:—"A succulent or pulpy fruit containing naked seeds, or, in more technical language, a succulent or pulpy pericarp, or seed-vessel without valves, containing several seeds, which are naked, that is, which have no covering but the pulp and rind. It is commonly round or oval. But in popular language, *berry* extends only to smaller fruits, as strawberry, gooseberry, &c., containing seeds or granules. An indehiscent pulpy pericarp, many celled and many seeded; the attachment of the seeds lost at maturity, and the seeds remaining scattered in the pulp."

Berries are used in some of the processes of manufacture, but they are not of much importance.

Bay Berries.—The fruit of the *Laurus nobilis*, or the sweet bay. Both the leaves and the fruit are employed as flavourings. A volatile oil, the *oil of sweet bay*, is obtained by distillation with water; and a fixed oil, by bruising the berries, and boiling them for some hours in water; this oil, called also *Laurel fat*, is imported from Italy.

Turkey Yellow Berries.—The unripe fruit of the *Rhamnus infectorius*. They are used in calico printing, producing a lively but fugitive yellow colour.

Persian Yellow Berries.—These are said to be produced by the same species of plant; but the colour is considered more permanent, and they fetch higher prices.

Berries of Avignon.—Another name given to the Turkey and Persian berries.

Juniper Berries.—The fruit of the *Juniperus communis*. They are chiefly used for flavouring gin and some spirituous cordials, and in the preparation of some pharmaceutical articles, as the oil of juniper and the compound spirits of juniper.

Bear Berry.—The fruit of the *Uva ursi*. The leaves only are used medicinally.

Myrobolans.—The fruit of a tree which grows in India. It has a pale-yellow colour when new, but becomes darker by age, and then resembles dried plums. It contains tannin, and has hence been used in dyeing.

In 1864 we *imported*:—

	cwts.	Computed real value.

BERTHOLLETIA. A plant of the natural order *Lecythideæ*, the *Bertholletia excelsa*. It is a tree of large dimensions, forming extensive forests on the banks of the Orinoco. The Portuguese of Para have for a long time driven a great trade with the nuts of this tree, which the natives call *Iuvia*, and the Spaniards *Almendron*. They send cargoes to French Guiana, whence they are shipped for England and Lisbon.

Digitized by Google

The kernels yield a large quantity of oil well suited for lamps.—*Humboldt and Bonpland.*

BERYL. (*Béril*, Fr.; *Beryl*, Germ.; *Smaragd*, Ital.) A beautiful mineral or gem, usually of a green colour of various shades, passing into honey yellow and sky blue.

Beryl and emerald are varieties of the same species, the latter including the rich green transparent specimens which owe their colour to oxide of chrome; the former those of other colours produced by oxide of iron. Gmelin gives the composition of beryl as:—

Silica	69·70
Alumina	17·60
Glucine	13·39
Red oxide of iron	0·24

"Beryls of gigantic size have been found in the United States, at Acworth and Grafton, New Hampshire, and Royalston, Mass. One beryl from Grafton weighs 2900 lbs.; it is 32 inches through in one direction, and 22 in another transverse, and is 4 feet 3 inches long. Another crystal from this locality, according to Professor Hubbard, measures 45 inches by 24 in its diameters, and a single foot in length; by calculation, weighs 1076 lbs., making it, in all, nearly 2½ tons. At Royalston, one crystal exceeded a foot in length."—*Dana.*

False Beryls of Commerce.—Some of the natural crystals of phosphate of lime are introduced as beryls. The *Apatite* is sometimes called the *Saxony beryl.* The *Chrysolite*, known by the Germans as the *Pierre d'Asperge*, is also sold as the beryl.

BETEL. A compound, in universal use in the East, consisting of the leaf of the betel-pepper, with the betel-nut, a little catechu, and some chunam (lime obtained by calcining shells). This is almost universally used throughout central and tropical Asia; the people are unceasingly masticating the betel. The leaf of the pepper vine (*Piper betel*), is extensively cultivated throughout tropical Asia, and forms a large article of Eastern traffic.

BETEL-NUT, or ARECA. The fruit of the *Areca catechu*, which is eaten both in its ripe and its unripe state.

BÉTON. The French name for concrete. Self-slacked hydraulic lime is mixed with sand, and when the mixture is complete it is beaten up with the ballast. See CONCRETE.

BEUHEYL. A mining term, signifying *a living stream.* It is applied by the tin miners to any portion of a lode or of the rock which is impregnated with tin.

BEZOAR. (The most probable etymology of the word is from the Persian *Pâdzahr*, i. e. expelling poison.—*Penny Cyclopædia.*) A concretion found in the stomach of animals of the goat kind; it is said to be especially produced by the *Capra gazella.* The finest bezoar is brought to India from Borneo and the shores of the Persian Gulf. The *Capra Ægagrus*, or wild goat of Persia producing this concretion, which, by way of eminence, was called the *Lapis bezoar orientalis.* The bezoars, which were supposed to cure all diseases, have been found, by the analyses of Fourcroy and Vauquelin and of Proust, to be nothing more than some portions of the food of the animal agglutinated into a ball with phosphate of lime.

Fossil bezoar is found in Sicily, in sand and clay pits. They are concretions of a purple colour around some, usually organic, body, and the size of a walnut. Fossil bezoar is sometimes called *Sicilian earth*; and it appears to be of a similar character to Armenian bole.

Bezoar Mineral.—An old preparation of the oxide of antimony.

BIBIRU and BIBIRINE. See GREENHEART TREE.

BICARBONATES. The ordinary carbonates of potash and soda have a strong alkaline reaction and caustic taste, making them unfit for many purposes where a soluble carbonate is required. Moreover, there are many uses to which they are applied, rendering it desirable that as large an amount of gas as possible should be given off on the addition of a stronger acid.

Bicarbonate of Potash.—There are several modes of converting the carbonate into bicarbonate. The most economical is by exposing the salt to a current of carbonic acid. For this purpose some manufacturers place it, slightly moistened, on stoneware trays, and allow the vapours of burning coke to travel slowly over it. The sources of the gas used in this manufacture will vary according to the locality in which it is undertaken. It is not unusual to produce it by the action of sulphuric acid on limestone. The gas generated in fermentation has been employed, and even that which in some places issues from the earth. The bicarbonate of potash is far less soluble than the carbonate, as it requires four parts of cold water for solution, whereas the carbonate dissolves in 0·9 of its weight of water at 54° F. Consequently, if a strong

Digitized by Google

solution is saturated with carbonic acid, the bicarbonate crystallises out. When common pearl ashes are dissolved in water, and the gas is passed in, a large quantity of a white precipitate is often thrown down; it consists chiefly of silica, but often contains alumina and other matters. Considerable heat is developed when moistened carbonate of potash is exposed to a current of carbonic acid gas. When carbonate of potash is dissolved in water, and gradually treated with acetic acid, so as to form acetate of potash, by no means the whole of the carbonic acid is expelled, and a point is arrived at when a considerable quantity of crystals is deposited; they consist of very pure bicarbonate of potash. In making acetate of potash on the large scale, the quantity of crystalline precipitate obtained in this manner is sometimes very large. Bicarbonate of potash is usually tolerably pure. If well crystallized, all the impurities remain in the mother-liquor, and on heating to redness almost exactly the theoretical amount of residue is left, viz. 69·05 per cent. Crystallised bicarbonate of potash always contains one equivalent of water, its formula being $KO, 2CO^2 + HO$.

Bicarbonate of Soda. — This salt is obtained by the same methods as the salt of potash. The crystals have a corresponding formula to the potash salt; namely, $NaO, 2CO^2 + HO$. It requires about 13 parts of water at 60° to dissolve it. When pure, 100 parts leave 63·18 of NaO, CO^2 on ignition.

The bicarbonates of potash and soda lose carbonic acid by the boiling of an aqueous solution.

Modern theoretical chemists regard carbonic acid as being bibasic, the true formula being C^2O^4, instead of CO^2. There can be little doubt that this view is the correct one, and it has the advantage of explaining why the bicarbonates are neutral instead of acid salts. Moreover, C^2O^4 corresponds to 4 volumes, like organic substances generally; whereas, if we assume CO^2 as one atom of the gas, we are compelled to admit a 2-volume formula. — C. G. W.

BIDERY. An Indian alloy of considerable interest, named Bidery from Bider, a city N.E. of Hyderabad. Many articles are made, remarkable for elegance of form and for gracefully-engraved patterns. Although the groundwork of this composition appears of a blackish colour, its natural tint is that of pewter or zinc.

Dr. Heyne says it is composed of, copper, 16; lead, 4; tin, 2; and to every 3 ounces of alloy 16 ounces of spelter (that is, of zinc) are added, when the alloy is melted for use. To give the esteemed black colour and to bring out the pattern, it is dipped in a solution of sal ammoniac, saltpetre, common salt, and blue vitriol. Dr. Hamilton saw, zinc, 12,360 grains; copper, 400; and lead, 414; melted together under a mixture of resin and bees' wax introduced into the crucible to prevent calcination; it was then poured into moulds of baked clay, and the articles handed over to be turned in a lathe. Though called bidery and sometimes vidry, it is manufactured in other places. In some parts of the Nizam's dominions, specimens were obtained, for the Exhibition of 1851, of great beauty. Bidery does not rust, yields little to the hammer, and breaks only when violently beaten. According to Dr. Hamilton, bidery is not nearly so fusible as zinc or tin, but melts more easily than copper.—*Dr. Royle, Lecture on the Great Exhibition.*

BIG. See BARLEY.

BIJOUTRY. (*Bijouterie*, Fr.) Jewellery;—the manufacture of and dealing in jewellery. This work is not the place in which to describe the almost endless variety of articles which come under this denomination. The principal places for the manufacture, in England, are Birmingham and London. The trade in jewellery forms one of the most important branches of French commerce; on which a French writer says: "La bijouterie est une des branches les plus importantes du commerce français, et c'est elle qui constate, de la manière la plus évidente, notre superiorité dans les arts du dessin et les progrès toujours croissans de l'industrie Parisienne. Dans cette partie essentielle, elle n'a pas de rivaux, et elle rend tributaire de notre pays presque toute l'Europe, et une grande partie de l'Asie et de l'Amérique."

The ordinary practice has been to divide articles of this character into two principal kinds — fine jewellery, and false jewellery (*bijoutier en fin* and *bijoutier en faux*). Another division, among the French jewellers especially, has been to adopt four classes: 1, fine jewellery, which is all gold; 2, silver jewellery; 3, false jewellery; and, 4, jewellery of steel or iron.

In the article ALLOYS will be found the quantity of the baser metal which is permitted to be combined with gold; and also the proportions of the alloys forming the brasses which are employed in the false jewellery.

Under their respective heads the true gems will be described (see DIAMOND, EMERALD, &c.); and under GEMS, ARTIFICIAL, the imitations of them; many of the false, so nicely representing the peculiarities of the true gems as to deceive even the practised eye. The hardness is, however, an unfailing test; if, therefore, any gem is

Digitized by Google

found to be scratched with a steel file, we may depend on its being artificial. See also PEARLS, ARTIFICIAL; LAPIDARY WORK; GLASS, &c.

BILE. (*Bile*, Fr.; *Galle*, Germ.) The secreted liquor of the liver in animals.

Bile (ox's) is composed, according to Berzelius, of:—

1. Biline, fellinic acid, and fat of gall	8·00
2. Mucus	0·30
3. Alkali combined with biline, &c.	0·41
4. Muriate of soda, extractive matter	0·74
5. Phosphate of soda, do. of lime, &c.	0·11
6. Water	90·44
	100·00

Thenard's analysis gives:—

1. Resin of bile and picromel (acid gallenate of soda)	10·54
2. Colouring matter	0·50
3. Soda	0·50
4. Phosphate of soda	0·25
5. Muriate of soda	0·40
6. Sulphate of soda	0·10
7. „ „ lime	0·15
8. Traces of oxide of iron	
9. Water	87·56
	100·00

Strecker and Mulder have published two treatises on ox-gall. The two views advocated by these chemists will be found in the "Annual Report of the Progress of Chemistry of Liebig and Kopp," translated by Hofmann and De la Rue.

The analyses of Benach ("Ann. Ch. Phar.") give the following as the composition of the gall of several animals:—

	Carbon.	Hydrogen.	Nitrogen.	Sulphur.	Ash.
Calves	55·4	7·7	3·3	4·9	13·15
Sheep	57·3	7.8	3·9	5·7	11·86
Goats	57·3	8·2	—	5·2	13·21
Bears	57·7	8·3	—	5·8	8·42
Fowls	57·5	8·3	3·5	5·0	10·99
Fish	56·0	8·1	2·5	5·6	14·11

Heintz remarks (Poggendorff's "Annalen"), that the change of colour sometimes produced—for it does not appear always—by nitric acid in liquids containing bile (first green, then blue, violet, red, and lastly, yellow), is occasioned only by the colouring matter, which Berzelius has named *cholepyrrhin*, and not by the essential constituents of the bile, and can therefore be regarded only as a test for the presence of this substance.

For the chemical examination of bile, see Watts' "Dictionary of Chemistry;" for its uses in the arts, see GALL.

BIND. The name by which many of the coal measure shales are locally known in many districts. They are generally more or less bituminous, and calcareous. Since so much attention has been directed to the production of petroleum, many of those "binds" have been subject to distillation, with variable results. See PETROLEUM.

BINDING COAL. See COAL.

BIRDLIME. (*Glu*, Fr.; *Vogelleim*, Germ.) The best birdlime may be made from the middle bark of the holly boiled seven or eight hours in water till it is soft and tender, then laid by heaps in pits under ground, and covered with stones after the water is drained from it. There it must be left during two or three weeks, to ferment in the summer season, and watered, if necessary, till it passes into a mucilaginous state. It is then to be pounded in a mortar to a paste, washed in running water, and kneaded till it be free from extraneous matters. It is next left for four or five days in earthen vessels to ferment and purify itself, when it is fit for use. Birdlime may be made by the same process from the mistletoe (*Viburnum Lantana*), young shoots of elder, and the barks of other vegetables, as well as from most parasitical plants.

Good birdlime is of a greenish colour and sour flavour, somewhat resembling that of linseed oil—gluey, stringy, and tenacious. By drying in the air it becomes brittle, and may be powdered; but its viscosity may be restored by moistening it. It contains resin, mucilage, a little free acid, colouring and extractive matter. The resin has been called viscine.

Macaire has examined a substance which exudes from the receptacle and involucre

Digitized by Google

of the *Atractylis gummifera*, and describes it as the pure matter of birdlime, which he calls viscine. Common birdlime may be regarded as a mixture of *viscine*, vegetable mucilage, and vinegar.

The mistletoe yields a peculiar viscid gluey substance, consisting of a green wax and birdlime.

BISCUITS. Biscuit baking constitutes two separate branches of manufacture,—namely, that of ordinary biscuit, or, so to speak, biscuit "proper," for maritime purposes, and that of fancy biscuits. Ordinary, or sailors', biscuit consists of only flour and water kneaded into a paste, cut in the proper shape, docked, and baked in an oven; fancy biscuits consist also of flour and water, but with an addition of butter, sugar, eggs, spices, or "flavourings," all or either of them according to the kind.

Ships' biscuits are now made by machinery, and one of the reasons for this has been that the manual preparation of them was too slow and too costly during the French war. A landsman knows very little of the true value of a biscuit: with a seaman, biscuit is the only bread that he eats for months together. There are many reasons why common loaves of bread could not be used during a long voyage: because, containing a fermenting principle, they would soon become musty and unfit for food if made previous to the voyage, while the preparation of them on board ship is subject to insuperable objections. Biscuits contain no leaven, and, when well baked throughout, they suffer little change during a long voyage.

The allowance of biscuit to each seaman on board a queen's ship is a pound per day (averaging six biscuits to the pound). The supply of a man-of war for several months is, consequently, very large; and it often happened during the long war that the difficulty of making biscuits fast enough was so great, that at Portsmouth waggon loads were unpacked in the streets and conveyed to the ships.

We shall now describe the mode of making biscuits by hand, and afterwards speak of the improved method. The bakehouse at Gosport contained nine ovens, and to each was attached a gang of five men,—the "turner," the "mate," the "driver," the "breakman," and the "idleman." The requisite proportions of flour and water were put into a large trough, and the "driver," with his naked arms, mixed the whole up together into the form of dough—a very laborious operation. The dough was then taken from the trough, and put on a wooden platform called the break: on this platform worked a lever called the break-staff, five or six inches in diameter, and seven feet long; one end of this was loosely attached by a kind of staple to the wall, and the breakman, riding or sitting on the other end, worked this lever to and fro over the dough by an uncouth jumping or shuffling movement. When the dough had become kneaded by this barbarous method into a thin sheet, it was removed to the moulding board and cut into slips by means of an enormous knife; these slips were then broken into pieces, each large enough for one biscuit, and then worked into a circular form by the hand. As each biscuit was shaped it was handed to a second workman, who stamped the king's mark, the number of the oven, &c., on the biscuit. The biscuit was then docked, that is, pierced with holes by an instrument adapted to the purpose. The finishing part of the process was one in which remarkable dexterity was displayed. A man stood before the open door of the oven, having in his hand the handle of a long shovel called a peel, the other end of which was lying flat in the oven. Another man took the biscuits as fast as they were formed and stamped, and jerked or threw them into the oven with such undeviating accuracy that they should always fall on the peel. The man with the peel then arranged the biscuits side by side over the whole floor of the oven. Nothing could exceed (in manual labour alone) the regularity with which this was all done. Seventy biscuits were thrown into the oven and regularly arranged in one minute, the attention of each man being vigorously directed to his own department; for a delay of a single second on the part of any one man would have disturbed the whole gang. The biscuits do not require many minutes' baking; and as the oven is kept open during the time that it is being filled, the biscuits first thrown in would be overbaked were not some precaution taken to prevent it. The moulder therefore made those which were to be first thrown into the oven larger than the subsequent ones, and diminished the size by a nice gradation.

The mode in which, since about the year 1831, ships' biscuits have been made by machinery invented by T. T. Grant, Esq., of the Royal Clarence Yard, is this:—The meal or flour is conveyed into a hollow cylinder four or five feet long and about three feet in diameter, and the water, the quantity of which is regulated by a gauge, admitted to it; a shaft, armed with long knives, works rapidly round in the cylinder, with such astonishing effect that in the short space of six minutes, 450 lbs. of dough are produced, infinitely better made than that mixed by the naked arms of a man. The dough is removed from the cylinder and placed under the breaking rollers; these latter, which perform the office of kneading, are two in number, and weigh 15 cwts. each;

Digitized by Google

they are rolled to and fro over the surface of the dough by means of machinery, and in five minutes the dough is perfectly kneaded. The sheet of dough, which is about two inches thick, is then cut into pieces half a yard square, which pass under a second set of rollers, by which each piece is extended to the size of six feet by three, and reduced to the proper thickness for biscuits. The sheet of dough is now to be cut up into biscuits; and no part of the operation is more beautiful than the mode by which this is accomplished. The dough is brought under a stamping or cutting-out press, similar in effect, but not in detail, to that by which circular pieces for coins are cut out of a sheet of metal. A series of sharp knives are so arranged that, by one movement, they cut out of a piece of dough a yard square about sixty hexagonal biscuits. The reason for a hexagonal (six-sided) shape is, that not a particle of waste is thereby occasioned, as the sides of the hexagonals accurately fit into those of the adjoining biscuits, whereas circular pieces cut out of a large surface always leave vacant spaces between. That a flat sheet can be divided into hexagonal pieces without any waste of material is obvious.

Each biscuit is stamped with the queen's mark, as well as punctured with holes, by the same movement which cuts it out of the piece of dough. The hexagonal cutters do not sever the biscuits completely asunder, so that a whole sheet of them can be put into the oven at once on a large peel, or shovel, adapted for the purpose. About 15 minutes are sufficient to bake them; they are then withdrawn and broken asunder by the hand.

The corn for the biscuits is purchased at the markets, and cleaned, ground, and dressed at the Government mills; in quality it is a mixture of fine flour and middlings, the bran and pollard being removed. The ovens for baking are formed of fire-brick and tile, with an area of about 160 feet. About 112 lbs. weight of biscuits are put into the ovens at once. This is called a suit, and is reduced to about 110 lbs. by the baking. From 12 to 16 suits can be baked in each oven every day, or after the rate of 224 lbs. per hour. The men engaged are dressed in clean check shirts and white linen trousers, apron, and cap, and every endeavour is made to observe the most scrupulous cleanliness.

We may now make a few remarks on the comparative merits of the hand and the machine processes. If the meal and the water with which the biscuits are made be not thoroughly mixed up, there will be some parts moister than others. Now, it was formerly found that the dough was not well mixed by the arms of the workman; the consequence of which was, that the dry parts became burnt up, or else that the moist parts acquired a peculiar kind of hardness which the sailors called "flint:" these defects are now removed by the thorough mixing and kneading which the ingredients receive by the machine.

We have seen that 450 lbs. of dough may be mixed by the machine in three minutes and kneaded in six minutes; we need hardly say how much quicker this is than men's hands could effect it. The biscuits are cut out and stamped 60 at a time, instead of singly: besides the time thus saved, the biscuits become more equally baked, by the oven being more speedily filled. The nine ovens at Gosport used to employ 45 men to produce about 1500 lbs. of biscuit per hour; 16 men and boys will now produce, by the same number of ovens, 2240 lbs. of biscuits (one ton) per hour.

The comparative expense is thus stated:—Under the old system, wages and wear and tear of utensils cost about 1*s.* 6*d.* per cwt. of biscuit; under the new system, the cost is 5*d.*

The bakehouses at Deptford, Gosport, and Plymouth could produce 7000 or 8000 tons of biscuits annually, at a saving of 12,000*l.* per annum from the cost under the old system. The advantages of machine-made over hand-made biscuits, therefore, are many—quality, cleanliness, expedition, cheapness, and independence of Government contractors.

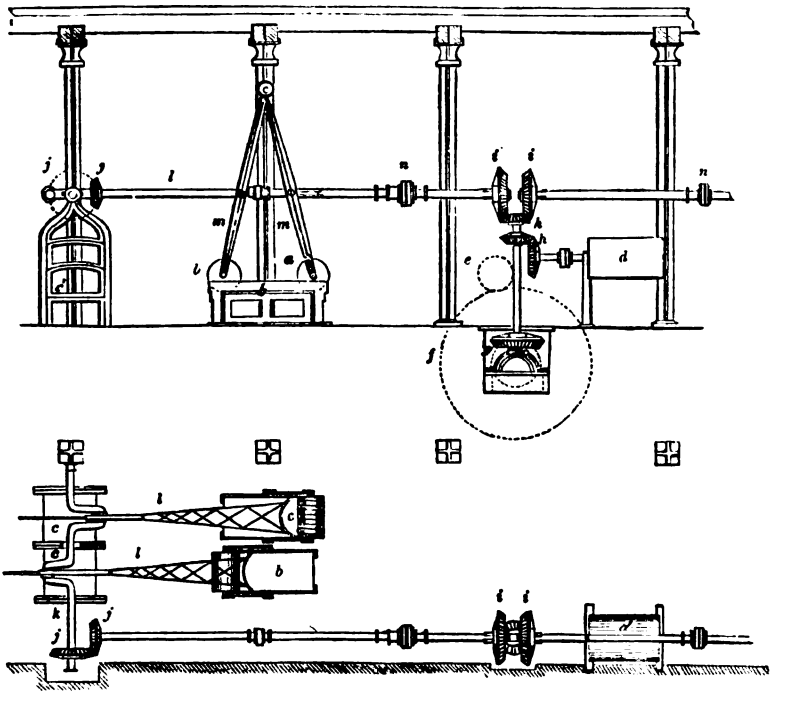
Fig. 159 represents the biscuit machinery as executed beautifully by Messrs. Rennie, engineers. *a* is the breaker roller, table, and toller; *b*, the finishing roller, table, and roller; *c c*, docking machines for stamping out the biscuits; *d*, mixing machine for making the dough; *e*, spur pinion to engine shaft; *f*, spur-wheel; *g g*, bevel mitre wheels, to give the upright motion; *h h*, bevel wheels for working the mixing machine; *i i i*, ditto, for communicating motion to the rolling machines, *j j*; *k*, the crank shaft; *l l*, connecting rods; *m m*, pendulums for giving motion to rollers; *n n*, clutches for connecting either half of the machinery to the other.

The manufacture of fancy biscuits, which in former times was confined to the pastry-cook and confectioner, has of late years assumed considerable importance, and several firms are now exclusively engaged in this branch of industry, the products of which are sold under an extraordinary variety of names. Some of these, namely, the "plain biscuit, arrow-root, captain, brown meal, cinnamon, caraway, vanilla biscuits," &c., are intelligible enough; but, if we except "Abernethy biscuit, maccaroons, and

Digitized by Google

cracknels," with the names of which the public, from long usage, are familiar, the rest of the products of the modern biscuit baker, "Africans, Jamaica, Queen's routs,

159



ratafias, Bath and other sorts of olivers, exhibition, rings and fingers, pic-nics, cuddy," &c., &c., forms a list of upwards of eighty fanciful names, all expressive of articles of different form, appearance, and taste, made of nearly the same materials, with but little variation in the proportion in which they are used,— the principal ingredients in all being flour and water, butter, milk, eggs, and caraway, nutmeg, cinnamon, or mace, or ginger, or essence of lemon, neroli, or orange-flower water, called, in technical language, "flavourings." The kneading of these materials is always performed by a kneading or mixing machine. The dough or paste produced is passed several times between two revolving cylinders adjusted at a proper distance, so as to obtain a flat, perfectly homogeneous mass, slab, or sheet. This is transferred to a stamping or cutting machine, consisting of two cylinders, through which the sheet of homogeneous paste has to pass, and by which it is laminated to the proper thickness, and at the same time pushed under a stamping and docking frame, which cuts it into discs, or into oval or otherwise shaped pieces, as occasion may require. The stamps or cutters in the frame being internally provided with prongs, push the cut pieces of dough, or raw cakes, out of the cutting frame, and at the same time dock the cakes, or cut pieces, with a series of holes, for the subsequent escape of the moisture, which, but for these vents, would distort and spoil the cake or biscuit when put in the oven. The temperature of the oven should be so regulated as to be perfectly uniform, neither too high nor too low, but just at such a heat as is sufficient to give the biscuits a light brown colour. For such a purpose the hot water oven of Mr. Perkins, or that of Mr. Roland, is the best that can possibly be used. (See BREAD.) Roland's oven offers the peculiar advantage that, by turning the screw, the sole of the oven can be brought nearer to the top, and a temperature is thus obtained suitable for baking thoroughly, without burning, the thinnest cakes.

One of the most curious branches of the baker's craft is the manufacture of gingerbread, which contains such a proportion of molasses that it cannot be fermented by means of yeast. Its ingredients are flour, molasses or treacle, butter, common potashes,

Digitized by Google

and alum. After the butter is melted, and the potashes and alum are dissolved in a little hot water, these three ingredients, along with the treacle, are poured among the flour which is to form the body of the bread. The whole is then incorporated by mixture, and kneading into a stiff dough. Of these five constituents the alum is the least essential, although it makes the bread lighter and crisper, and renders the process more rapid; for gingerbread, dough requires to stand over for several days, some 8 or 10, before it acquires the state of porosity which qualifies it for the oven; the action of the treacle and alum on the potashes, in evolving carbonic acid, seems to be the gassifying principle of gingerbread; for if carbonate of potash is withheld from the mixture, the bread, when baked, resembles, in hardness, a piece of wood.

Treacle is always acidulous. Carbonate of magnesia and soda may be used as substitutes for the potashes. Dr. Colquhoun has found that carbonate of magnesia and tartaric acid may replace the potashes and the alum with great advantage, affording a gingerbread fully more agreeable to the taste, and much more wholesome than the common kind, which contains a notable quantity of potashes. His proportions are 1 lb. of flour, ½ of an ounce of carbonate of magnesia, and ½ of an ounce of tartaric acid, in addition to the treacle, butter, and aromatics, as at present used. The acid and alkaline earth must be well diffused through the whole dough; the magnesia should, in fact, be first of all mixed with the flour. The melted butter, the treacle, and the acid dissolved in a little water, are poured all at once amongst the flour, and kneaded into a consistent dough, which being set aside for half an hour or an hour, will be ready for the oven, and should never be kept unbaked for more than 2 or 3 hours. The following more complete recipe is given by Dr. Colquhoun for making thin gingerbread cakes:—Flour 1 lb., treacle ½ lb., raw sugar, ½ lb., butter 2 ounces, carbonate of magnesia ½ ounce, tartaric acid ½ ounce, ginger ½ ounce, cinnamon ½ ounce, nutmeg 1 ounce. This compound has rather more butter than common thin gingerbread. In addition to these, yellow ochre is frequently added by cheap gingerbread makers, and altogether this preparation, more generally consumed by children, is very objectionable.

Within the last six years there has been a very remarkable development of the trade in biscuits. Biscuits of all sorts, and really many curious and agreeable varieties, are now manufactured on a large scale, and machinery has been created to facilitate the process. This development of the biscuit trade will be shown by our exports. Fancy bread is named in the returns in connection with biscuits, but this is really but an exceeding small portion of the whole. Our exports of biscuits and bread in 1864 were:—

BISMUTH. (*Bismuth*, Fr.; *Bismuth*, Germ.) The following are the principal ores of bismuth; the first is the source of the metal used in the arts:—

Digitized by Google

Bismuth, Native, is whitish, with a faint reddish tinge, and a metallic lustre which is liable to tarnish. Streak, silver-white. Hardness, 2 to 2·5; specific gravity, 9·727 It is brittle when cold, but slightly malleable when heated. It generally occurs in a dendritic form. It fuses readily at 476° F. Beautiful crystals can be formed artificially by fusion and subsequent slow cooling.

Native bismuth has been found associated with other minerals: in Cornwall, at Huel Sparnon, near Redruth, when that mine was worked; at Trugoe Mine, near St. Colomb (Greg), and at the Consolidated Mines, St. Ives, Caldbeck Fells, in Cumberland, with ores of cobalt.

Bismuthine, or sulphuret of bismuth, occurs either in acicular crystals, or with a foliated, fibrous structure. It is isomorphous with stibnite. Hardness, 2 to 2·5; specific gravity, 6·4 to 6·9. It is composed of bismuth, 81·6; sulphur, 18·4. It fuses in the flame of a candle.

Bismuthine occurs in Cornwall, at Botallack, and associated with tin at St. Just, and with copper at the mines near Redruth and Camborne.

Bismuth Ochre.—A dull earthy mineral, found in the Royal Restormel Iron Mine, and in small quantities in the parish of Roach, in Cornwall. Its composition is stated by Lampadius to be:—

Oxide of bismuth	86·4
Oxide of iron	5·1
Carbonic acid	4·1
Water	3·1

Telluric Bismuth.—Tetradymite,—occurs in Cumberland, at Brandy Gill, Carrock Fells (Greg). Its composition is:—

Bismuth	83·30
Tellurium	6·65
Sulphur	6·13
Selenium	1·22

Acicular Bismuth.—Aikinite—called also Needle Ore, and the plumbo-cupriferous sulphide of bismuth—is composed of sulphur, 16; bismuth, 34·62; lead, 35·69; copper, 11·79.

Carbonate of Bismuth.—Bismutite. This ore is composed of a mechanical mixture of the carbonates of bismuth, of iron, and of copper.

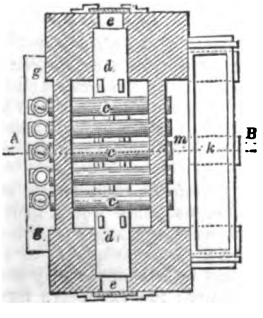
Cupreous Bismuth.—Tannenite, is sulphur, 18·83; bismuth, 62·16; copper, 18·72.

This metal is also found associated with selenium and tellurium.

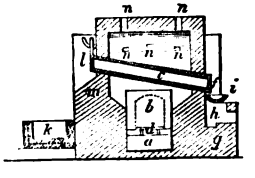
Bismuth, which was known as *Marcasite* and as tin glance, was shown to be a metal "somewhat different from lead" by G. Agricola, in 1546. It was studied by Stahl and Dufay; and still more minutely by Pott and Geoffroy, about the middle of the last century.

This metal, the demand for which is limited, is chiefly procured in Saxony, from the mines of Schneeberg; where it occurs mixed with cobalt speiss, in the proportion of about 7 per cent. In the metallurgical works at Schneeberg the metal is obtained by means of a peculiar furnace of liquation. This furnace is represented in *figs.* 160 and 161, of which the first is a view from above, the second a view in front; and *fig.* 162 is a transverse section on the dotted line A, B, of *fig.* 160; *a*, is the ash-pit; *b*, the fire-place; *c*, the eliquation pipes; *d*, the grate, of masonry or brickwork, upon which the fuel is thrown through the fire-door, *e e*. The anterior deeper-lying

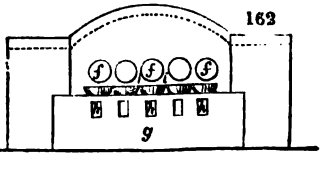
160



161



162



Digitized by Google

orifice of the eliquation pipes is closed with the clay plate, *f*, which has beneath a small circular groove, through which the liquefied metal flows off; *g* is a wall extending from the hearth-sole nearly to the anterior orifices of the liquation-pipes, in which wall there are as many fire-holes, *h*, as there are pipes in the furnace; *i* are iron pans which receive the fluid metal; *k*, a wooden water-trough, in which the bismuth is granulated and cooled; *l*, the posterior and higher lying apertures of the eliquation pipes, shut merely with a sheet-iron cover. The granulations of bismuth drained from the posterior openings fall upon the flat surfaces *m*, and then into the water-trough. *n*, *n* are draught-holes in the vault between the two pipes, which serve for increasing or diminishing the heat at pleasure.

The ores to be eliquated (sweated) are sorted by hand from the gangue, broken into pieces about the size of a hazel nut, and introduced into the ignited pipes; one charge consisting of about ½ cwt.; so that the pipes are filled to half their diameter, and three-fourths of their length. The sheet-iron door is shut, and the fire strongly urged, whereby the bismuth begins to flow in ten minutes, and falls through the holes in the clay-plates into hot pans containing some coal-dust. Whenever it runs slowly, the ore is stirred round in the pipes, at intervals during half an hour, in which time the liquation is usually finished. The residuum, called bismuth barley (*Graupen*), is scooped out with iron rakes into a water trough; the pipes are charged afresh; the pans, when full, have their contents cast into moulds, forming bars of from 25 to 50 lbs. weight. About 20 cwt. of ore are smelted in 8 hours, with a consumption of 63 Leipzic cubic feet of wood. The total production of Schneeberg, in 1830, was 9800 lbs. The bismuth thus procured by liquation upon the great scale contains no small admixture of arsenic, iron, and some other metals, from which it may be freed by solution in nitric acid, precipitation by water, and reduction of the sub-nitrated oxide by black flux. By exposing the crude bismuth for some time to a dull red heat, under charcoal, arsenic is expelled.

Bismuth is white, and resembles antimony, but has a reddish tint; whereas the latter metal has a bluish cast. It is brilliant, crystallises readily in small cubical facets, is very brittle, and may be easily reduced to powder. Its specific gravity is 9·83; and by hammering it with care, the density may be increased to 9·8827. It melts at 480° F., and may be cooled 6° or 7° below this point without fixing; but the moment it begins to solidify, the temperature rises to 480°, and continues stationary till the whole mass is congealed. When heated from 32° to 212°, it expands $\frac{1}{76}$ in length. When pure it affords a very valuable means of adjusting the scale of high-ranged thermometers. At strong heats bismuth volatilises, may be distilled in close vessels, and is thus obtained in crystalline laminæ.

The alloy of bismuth and lead in equal parts has a density of 10·709, being greater than the mean of the constituents; it has a foliated texture, is brittle, and of the same colour as bismuth. Bismuth, with tin, forms a compound more elastic and sonorous than the tin itself, and is therefore frequently added to it by the pewterers. With 1 of bismuth and 24 of tin, the alloy is somewhat malleable; with more bismuth it is brittle. When much bismuth is present, it may be easily parted by strong muriatic acid, which dissolves the tin, and leaves the bismuth in a black powder. It has been said that an alloy of tin, bismuth, nickel, and silver hinders iron from rusting.—*Erdmann's Journal.*

The alloy of bismuth with tin and lead was first examined by Sir I. Newton, and has been called ever since fusible metal. The French give to this alloy the name of *métal fusible de D'Arcet*, and thus claim for him the merit of the discovery of it. 8 parts of bismuth, 5 of lead, and 3 of tin, melted at the moderate temperature of 202° F.; but 2 of bismuth, 1 of lead, and 1 of tin, melt at 200·75° F., according to Rose. A small addition of mercury aids the fusibility. Such alloys serve to take casts of anatomical preparations.

An alloy of 1 bismuth, 2 tin, and 1 lead, is employed as a soft solder by the pewterers; and the same has been proposed as a bath for tempering steel instruments. Cake-moulds for the manufacture of toilet soaps are made of the same metal; as also excellent *clichés* for stereotype, of 3 lead, 2 tin, and 5 bismuth—an alloy which melts at 199° F. This compound should be allowed to cool upon a piece of pasteboard till it becomes of a doughy consistence, before it is applied to the mould to receive the impress of the stamp.

The employment of plates of fusible metal as safety *rondelles*, to apertures in the tops of steam boilers has been proposed in France, because they would melt and give way at elevations of temperature under those which would endanger the bursting of the vessel, the fusibility of the alloy being proportioned to the quality of steam required for the engine. It has been found, however, that boilers, apparently secured in this way, burst, while the safety discs remained entire; the expansive force of

Digitized by Google

the steam causing explosion so suddenly, that the fusible alloy had not time to melt or give way.

There are two, perhaps three, oxides of bismuth; the first and the third, or the sub-oxide and super-oxide, are merely objects of chemical curiosity. The oxide proper occurs native, and may be readily formed by exposing the metal to a red-white heat in a muffle, when it takes fire, burns with a faint blue flame, and sends off fumes which condense into a yellow pulverulent oxide. But an easier process than that now mentioned is to dissolve the bismuth in nitric acid, precipitate with water, and expose the precipitate to a red heat. The oxide thus obtained has a straw-yellow colour, and fuses at a high heat into an opaque glass of a dark-brown or black colour; but which becomes less opaque and yellow after it has cooled. Its specific gravity is as high as 8·211. It consists of 89·87 of metal and 10·13 of oxygen in 100 parts. The above precipitate, which is a sub-nitrate of bismuth, is called *pearl-white*, and is employed as a flux for certain enamels, as it augments their fusibility, imparting any colour to them. Hence it is used sometimes as a vehicle of the colours of other metallic oxides. When well washed, it is employed in gilding porcelain; being added in the proportion of one-fifteenth to the gold. But pearl-white is most used by ladies, as a cosmetic for giving a brilliant tint to a faded complexion. It is called *blanc de fard* by the French. If it contains, as bismuth often does, a little silver, it becomes grey or dingy coloured on exposure to light. When the oxide is prepared, by dropping the nitric solution into an alkaline lye in excess, if this precipitate is well washed and dried, it forms an excellent medicine; and is given, mixed with gum tragacanth, for the relief of cardialgia, or burning and spasmodic pains of the stomach.

Another sort of pearl-powder is prepared by adding a very dilute solution of common salt to the above nitric solution of bismuth, whereby a pulverulent sub-chloride of the metal is obtained in a light flocculent form. A similar powder of a mother-of pearl aspect may be formed by dropping dilute muriatic acid into the solution of nitrate of bismuth. The arsenic always present in the bismuth of commerce is converted by nitric acid into arsenic acid, which, forming an insoluble arseniate of bismuth, separates from the solution unless there be such an excess of nitric acid as to re-dissolve it. Hence the medicinal oxide, prepared from a rightly-made nitrate, can contain no arsenic. If we write with a pen dipped in that solution, the dry invisible traces will become legible on plunging the paper in water.

The nitrate of bismuth, mixed with a solution of tin and tartar, has been employed as a mordant for dyeing lilac and violet in calico printing.

Through the investigations which have been made by Dr. Faraday into the magnetic conditions of bodies, several new and remarkable conditions have been discovered. These may be familiarly explained, by stating that one class of bodies is influenced by magnets, as iron is, being *magnetic*. That is, if a bar of iron was hung up between the poles of a horse-shoe magnet, it would arrange itself along the line which unites the two poles; which line has been called the *axial line*. But if another class of bodies be selected, bismuth being at the head of this class, and suspended in the same way between the poles of the magnet, they arrange themselves across the axial line, or, as Faraday has termed it, *equatorially*, these bodies being called in distinction *dia-magnetic* bodies. See MAGNETISM, for a further account of these phenomena.

Bismuth may be regarded as the most remarkable of the dia-magnetic bodies, standing, indeed, at the head of the class, in the same way as iron does at the head of the magnetic order of substances.*

In Watts' "Dictionary of Chemistry" will be found various methods for the determination of bismuth. The following processes, however, appear so useful as to warrant their insertion in this place:—To detect small quantities of lead in bismuth, or in bismuth compounds, Chapman brings the somewhat flattened bead, reduced before the blowpipe, in contact with some moist basic nitrate of teroxide of bismuth, when, in a short time, in consequence of the reduction of the bismuth by the lead, arborescent sprigs of bismuth are formed around the test specimen. Since zinc and iron interfere with this reaction, they must be previously removed, the former by fusion with soda, the latter with soda and borax, in the reducing flame.

Lead and bismuth can easily be quantitatively separated from each other by the following method, proposed by Ullgren;—The solution of the two metals is precipitated by carbonate of ammonia, and the carbonates are then dissolved by acetic acid, and a blade of pure lead, the weight of which is ascertained beforehand, is plunged in the solution. This blade must be completely immersed in the liquor, The vessel is then corked up, and the experiment is left for several hours at rest.

* Consult De la Rive's Treatise on Electricity, translated by Charles V. Walker, F.R.S.

Digitized by Google

The lead precipitates the bismuth in the metallic form. When the whole of it is precipitated, the blade of lead is withdrawn, washed, dried, and weighed. The bismuth is collected on a filter, washed with distilled water which has been previously boiled, and cooled out of contact of the air; this metal is then treated with carbonate ammonia, and the precipitate which is left, after washing and ignition, is then weighed. The total loss of the metallic lead employed indicates how much oxide of lead must be subtracted from the total weight of the protoxide of lead obtained.

Oxide of bismuth can be separated, by means of sulphohydric acid, from all the oxides which cannot be precipitated from an acid solution by this reagent.

The mines of Schneeberg produce annually about 4000 kilogrammes; those of Johann-Georgenstadt and the cobalt mines of Saxony, about 600 kilogrammes—equal to about 10,500 avoirdupois pounds.

In 1844 bismuth was sold at from 10*d.* to 2*s.* the pound; in July 1861 it had reached the high price of 20*s.* the pound; since which time it has been gradually falling back, until at the end of 1865 the price was 11*s.* the pound. This variation has been thus accounted for. Up to 1844 a large quantity of bismuth was produced in this country from cobalt ores in the old way of refining, but a new method was then introduced which necessitated the loss of nearly all the bismuth. In 1845 there was a large demand for a composition to make rollers for calico printers, which advanced the price. In 1858 the supply began to fall off, and in 1861-2 there was an increased demand for this metal for medicinal purposes, but this is really very trifling. A company was formed in London, within the last few years, under the guidance of a German, who professed to have the secret of transmuting the baser metals into gold. This company had works in the Belvedere Road, Lambeth, and as bismuth was considered essential in the process, they bought all they could lay hands on. This, it is believed, more than anything led to the rapid increase in the price of the metal. Of course the concern failed, and the shareholders are said to be selling their bismuth very cautiously to realise as much as possible.

BISTRE. (*Bistre*, Fr.; *Bister*, Germ.) A brown colour which is used in water-colours, in the same way as China ink. It is prepared from wood-soot, that of beech being preferred. The most compact and best burned parcels of soot are collected from the chimney, pulverised, and passed through a silk sieve. This powder is infused in pure water, and stirred frequently with a glass rod, then allowed to settle, and the water decanted. If the salts are not all washed away, the process may be repeated with warm water. The paste is now to be poured into a long narrow vessel filled with water, stirred well, and left to settle for a few minutes, in order to let the grosser parts subside. The supernatant part is then to be poured off into a similar vessel. This process may be repeated twice or thrice, to obtain a very good bistre. At last the settled deposit is sufficiently fine, and, when freed from its superatant water, it is mixed with gum-water, moulded into proper cakes and dried. It s not used in oil painting, but has the same effect in water-colours as brown pink has in oil.

Dr. MacCulloch objects to soot as a source of bistre, both from the carelessness used in collecting it, and the uncertainty of tone and colour. If the liquids resembling tar, obtained from the distillation of wood, be again carefully distilled, water, acetic acid, and hydro-carbonous substances, as naphtha, pass over, and leave a residuum—brown or black, pitch-like, or brittle—according to the time and temperature employed; by prolonging the heat with care, the brittle substance becomes a powder. Dr. MacCulloch states that, by care, bistre from wood tar may be obtained, having the fine properties of sepia with greath depth of colour.

The remarkable bronze-like varnish, with almost a metallic lustre, seen upon the interior of highland cottages, are bistre deposits from the smoke of peat.

BITTER ALMOND OIL. See ALMOND OIL.

BITTER ALMOND WATER. Water containing the oil of bitter almonds in solution. It should be prepared by distillation from the bitter almonds. It is however frequently made by first rubbing the essential oil of bitter almonds with magnesia and mixing this with water, or a solution of the oil in spirits of wine is simply added to the water and they are shaken together.

BITTER PRINCIPLE. *Amer*, Fr.; *Bitterstoff*, Germ.) The "bitter principles" consist of bodies which may be extracted from vegetable productions by the agency of water, alcohol, or ether. These are not of much importance in the arts, with a few exceptions. *Lupulin.*—For example, the bitter principle of the hop is used for preserving beer.

Quassin is the bitter principle of quassia; *Absinthin*, that of wormwood; and *Gentianin*, that of gentian. These are sometimes substituted for the hop.

Digitized by Google

For particulars of these, and numerous other bitter principles, see *Watts' Dictionary of Chemistry.*

The following list gives the more important of the bitter substances which have been used in the arts and in medicine. See the articles respectively :—

Name.	Part employed.	Country.	Observations.
Quassia	Wood	Surinam, E. Indies	Powerfully bitter
Wormwood	Herb	Great Britain	Ditto
Aloe	Inspissated juice	South Africa	Ditto
Angustura	Bark	South America	Ditto
Orange	-	South of Europe	Aromatic bitter
Acorus	Root	Ditto	Ditto
Carduus benedictus	Herb	Greek Archipelago	
Cascarilla	Bark	Jamaica	Ditto
Centaury	Herb	Great Britain	
Camomile	Flowers	Ditto	Ditto
Colocynth	Fruit	Levant	Intolerably bitter
Colombo	Root	East Africa	Very bitter
Fumitory	Herb	Great Britain	Ditto
Gentiana lutea	Root	Switzerland	Ditto
Ground Ivy	Herb	Great Britain	Ditto
Walnut	Peel	Ditto	Ditto with tannin
Iceland moss	Plant	Ditto	Ditto with starch
Hops	Scales of the female flowers.	Ditto	Aromatic bitter
Milfoil	Herb flowers	Ditto	
Satyrion, large-leaved	Herb	Ditto	
Rhubarb	Root	China, Turkey	Disagreeable odr.
Rue	Herb	Great Britain	Bitter and sharp
Tansy	Herb flowers	Ditto	Bitter & offensive
Trefoil, bitter	Herb	Ditto	
Simarouba	Bark	Guiana	
Bryony	Root	Great Britain	Sharp, bitter, nauseous.
Coffee	Seeds	Arabia	Agreeable

BITTER SPAR. A carbonate of lime and a carbonate of magnesia. See DOLOMITE.

BITUMEN, or ASPHALTUM. (*Bitume*, Fr.; *Erdpech*, Germ.) A black substance found in the earth, externally not dissimilar to coal. It is composed of carbon, hydrogen, and oxygen, like organic bodies; but its origin is uncertain. It has seldom been observed among the primitive or older strata, but abundantly in the secondary and alluvial formations.

Bitumen comprises several distinct varieties, of which the two most important are asphaltum and naphtha.

Asphaltum is solid, and of a black, or brownish-black, colour, with a conchoidal brilliant fracture, sometimes called *Bitumen of Judea.*

Naphtha.—Liquid and colourless when pure, with a bituminous odour.

There are also the *earthy*, or *slaggy mineral pitch—petroleum*—a dark coloured fluid variety, containing much naphtha, and *maltha*, or *mineral tar.*

Bitumen in all its varieties was known to the ancients. It was used by them, combined with lime, in their buildings. Not only do we find the ruined walls of temples and palaces in the East, with the stones cemented with this material, but some of the old Roman castles in this country are found to hold bitumen in the cement by which their stones are secured. At Agrigentum it was burnt in lamps, and called "Sicilian oil." The Egyptians used it for embalming.—*Dana.*

Springs of which the waters contain a mixture of petroleum, and the various minerals allied to it—as bitumen, asphaltum, and pitch—are very numerous, and are, in many cases, undoubtedly connected with subterranean heat, by the agency of which organic remains undergo some of those remarkable changes, which ultimately result in the formation of coal. Within a few years many discoveries have been made of sources of fluid bitumen and petroleum in both the old and new worlds. The importance of these natural products renders it advisable to comprehend a description of

Digitized by Google

them under one general head. In one locality there are said to be 520 wells, which yield annually 400,000 hogsheads of petroleum. See PETROLEUM.

Fluid bitumen is seen to ooze from the bottom of the sea on both sides of the island of Trinidad, and to rise up to the surface of the water. It is stated that, about seventy years ago, a spot of land on the western side of Trinadad, nearly half-way between the capital and an Indian village, sank suddenly, and was immediately replaced by a small lake of pitch. In this way, probably, was formed the celebrated Great Pitch Lake. Sir Charles Lyell remarks:—"The Orinoco has for ages been rolling down great quantities of woody and vegetable bodies into the surrounding sea, where, by the influence of currents and eddies, they may be arrested and accumulated in particular places. The frequent occurrence of earthquakes, and other indications of volcanic action in those parts, lend countenance to the opinion that these vegetable substances may have undergone, by the agency of subterranean fire, those transformations or chemical changes which produce petroleum; and this may, by the same causes, be forced up to the surface, where, by exposure to the air, it becomes inspissated, and forms the different varieties of pure and earthy pitch, or asphaltum, so abundant in the island."

The Pitch Lake is one and a half miles in circumference; the bitumen is solid and cold near the shores, but gradually increases in temperature and softness towards the centre, where it is boiling. The solidified bitumen appears as if it had cooled, as the surface boiled, in large bubbles. The ascent to the lake from the sea, a distance of three-quarters of a mile, is covered with a hardened pitch, on which trees and vegetables flourish; and about Point la Braye, the masses of pitch look like black rocks among the foliage: the lake is underlaid by a bed of mineral coal.—*Manross*, quoted by Dana.

The Earl of Dundonald remarks, that vegetation contiguous to the lake of Trinidad is most luxuriant. The best pine-apples in the West Indies (called black pines) grow wild amid the pitch.

Asphaltum is abundant on the shores of the Dead Sea. It occurs in some of the mines of Derbyshire, and has been found in granite, with quartz and fluor spar, at Poldice, in Cornwall. There is a remarkable bituminous lime and sandstone of the region of Bechelbronn and Lobsann, in Alsace. From the observations of Daubrée, we learn that probably this bitumen has had its origin as an emanation from the interior of the earth; and indeed, in Alsace, with the great elevated fissure of the sandstone of the Vosges, a fissure which was certainly open before the deposit of the Trias, but was not yet closed during the tertiary epoch, affording during this latter, moreover, an opportunity for the deposition of spathic iron ore, iron pyrites, and heavy spar.—*Annales des Mines.*

Elastic Bitumen, called also mineral caoutchouc and *elaterite*, was first observed in Derbyshire, in the forsaken lead mine of Odin, by Dr. Lister, in 1673, who called it a subterranean fungus. It was afterwards described by Hatchett. The analysis of this variety, by Johnston, gave the following as its composition:—

Carbon 85·47 - - - Hydrogen 13·28.

Two descriptions of elastic bitumen were analysed by M. Henry, fils ("Ann. des Mines"). He states the English to have been in brown masses, slightly translucid, of a greenish colour, soft, elastic, burning with a white flame, and giving off a bituminous odour, and of specific gravity 0·9 to 1·23, and obtained from Derbyshire.

The French elastic bitumen generally resembled the English, excepting that it was opaque, and floated on water. It was discovered at the coal mines of Montrelais.

	English.	French.
Carbon	0·5225	0·5826
Hydrogen	0·0749	0·0489
Nitrogen	0·0015	0·0010
Oxygen	0·4011	0·3675
	1·0000	1·0000

Of ordinary bitumen, we have analyses of two specimens; one by Ebelmen, who obtained his sample from the Auvergne; and the other by Boussingault, which was a Peruvian specimen:—

	Auvergne.	Peruvian.
Carbon	76·13	88·63
Hydrogen	9·41	9·69
Oxygen	10·34	1·68
Nitrogen	2·32	
Ash	1·80	
	100·00	100·00

Digitized by Google

On the employment of bitumen for pavements, Dr. Ure has the following remarks:—It is a very remarkable fact, in the history of the useful arts, that asphalt, which was so generally employed as a solid and durable cement in the earliest constructions upon record, as in the walls of Babylon, should for so many thousand years have fallen well nigh into disuse among civilised nations. For there is certainly no class of mineral substances so well fitted as the bituminous, by their plasticity, fusibility tenacity, adhesiveness to surfaces, impenetrability by water, and unchangeableness in the atmosphere, to enter into the composition of terraces, foot-pavements, roofs, and every kind of hydraulic work. Bitumen, combined with calcareous earth, forms a compact semi-elastic solid which is not liable to suffer injury by the greatest alternations of frost and thaw, which often disintegrate in a few years the hardest stone, nor can it be ground to dust and worn away by the attrition of the feet of men and animals, as sandstone, flags, and even blocks of granite are. An asphalt pavement, rightly tempered in tenacity, solidity, and elasticity, seems to be incapable of suffering abrasion in the most crowded thoroughfares; a fact exemplified of late in a few places in London, but much more extensively, and for a much longer time, in Paris.

The great Place de la Concorde (formerly Place Louis Quinze) is covered with a beautiful mosaic pavement of asphalt; many of the promenades on the Boulevards, formerly so filthy in wet weather, are now covered with a thin bed of bituminous mastic, free alike from dust and mud; the foot-paths of the Pont Royal and Pont Carousel, and the areas of the great public slaughter-houses, have been for several years paved in a similar manner with perfect success. It is much to be regretted that the asphalt companies of London, made the ill-judged, and nearly abortive, attempt to pave the carriage-way near the east end of Oxford Street, and especially at a moist season, most unpropitious to the laying of bituminous mastic. Being formed of blocks not more than three or four inches thick, many of which contained much siliceous sand, such a pavement could not possibly resist the crash and vibration of many thousand heavy drays, waggons, and omnibuses daily rolling over it. This failure can afford, however, no argument against rightly-constructed foot pavements and terraces of asphalt. Numerous experiments and observations have led me to conclude that fossil bitumen possesses far more valuable properties for making a durable mastic than the solid pitch obtained by boiling wood or coal tar. The latter, when inspissated to a proper degree of hardness, becomes brittle, and may be readily crushed into powder; while the former, in like circumstances, retains sufficient tenacity to resist abrasion. Factitious tar and pitch being generated by the force of fire, seem to have a propensity to decompose by the joint agency of water and air, whereas mineral pitch has been known to remain for ages without alteration.

Bitumen alone is not so well adapted for making a substantial mastic as the native compound of bitumen and calcareous earth, which has been properly called asphaltic rock, of which the richest and most extensive mine is unquestionably that of the Val de Travers, in the canton of Neufchâtel. This interesting mineral deposit occurs in the Jurassic limestone formation, the equivalent of the English oolite. The mine is very accessible, and may be readily excavated by blasting with gunpowder. The stone is massive, of irregular fracture, of a liver-brown colour, and is interspersed with a few minute spangles of calcareous spar. Though it may be scratched with the nail, it is difficult to break by the hammer. When exposed to a very moderate, heat it exhales a fragrant ambrosial smell, a property which at once distinguishes it from all compounds of factitious bitumen. Its specific gravity is 2·114, water being 1000, being nearly the density of bricks. It may be most conveniently analysed by digesting it in successive portions of hot oil of turpentine, whereby it affords 80 parts of a white pulverulent carbonate of lime, and 20 parts of bitumen in 100. The asphalt rock of Val de Travers seems therefore to be far richer than that of Pyrimont, which, according to the statement in the specification of Claridge's patent of November, 1837, contains "carbonate of lime and bitumen in about the proportion of 90 parts of carbonate of lime to about 10 parts of bitumen."

The calcareous matter is so intimately combined and penetrated with the bitumen as to resist the action not only of air and water for any length of time, but even of muriatic acid; a circumstance partly due to the total absence of moisture in the mineral, but chiefly to the vast incumbent pressure under which the two materials have been incorporated in the bowels of the earth. It would indeed be a difficult matter to combine, by artificial methods, calcareous earth thus intimately with bitumen, and for this reason the mastics made in this way are found to be much more perishable. Many of the factitious asphalt cements contain a considerable quantity of siliceous sand, from which they derive the property of cracking and crumbling down when trodden upon. In fact, there seems to be so little attraction between siliceous

Digitized by Google

matter and bitumen, that their parts separate from each other by a very small disruptive force.

Since the asphalt rock of Val de Travers is naturally rich enough in concrete bitumen, it may be converted into a plastic workable mastic of excellent quality for foot pavements and hydraulic works at very little expense, merely by the addition of a very small quantity of mineral or coal tar, amounting to not more than 6 or 8 per cent. The union between these materials may be effected in an iron cauldron, by the application of a very moderate heat, as the asphalt bitumen readily coalesces with the tar into a tenacious solid.

The mode adopted for making the asphalt pavement at the Place de la Concorde in Paris was as follows:—The ground was made uniformly smooth, either in a horizontal plane or with a gentle slope to carry off the water; the curb-stones were then laid round the margin by the mason, more than 4 inches above the level of the ground. This hollow space was filled to a depth of 3 inches with concrete, containing about a sixth part of hydraulic lime, well pressed upon its bed. The surface was next smoothed with a thin coat of mortar. When the whole mass had become perfectly dry, the mosaic pattern was set out on the surface, the moulds being formed of flat iron bars, rings, &c., about half an inch thick, into which the fluid mastic was poured by ladles from a cauldron, and spread evenly over.

The mastic was made in the following way:—The asphalt rock was first of all roasted in an oven, about 10 feet long and 3 broad, in order to render it friable. The bottom of the oven was sheet iron, heated below by a brisk fire. A volatile matter exhaled, probably of the nature of naphtha, to the amount of one-fortieth the weight of asphalt; after roasting, the asphalt became so friable as to be easily reduced to powder, and passed through a sieve having meshes of about one-fourth of an inch square.

The bitumen destined to render the asphalt fusible and plastic was melted, in small quantities at a time, in an iron cauldron, and then the asphalt in powder was gradually stirred in to the amount of 12 or 13 times the weight of bitumen. When the mixture became fluid, nearly a bucketful of very small, clean gravel, previously heated apart, was stirred into it; and, as soon as the whole began to simmer with a treacly consistence it was fit for use. It was transported in buckets, and poured into the moulds.

For the reasons above assigned, I consider this addition of rounded, polished, siliceous stones to be very injudicious. If anything of the kind be wanted to give solidity to the pavement, it should be a granitic or hard calcareous sand, whose angular form will secure the cohesion of the mass. I conceive also, that liquid bitumen in moderate quantity should be used to give toughness to the asphaltic combination, and prevent its being pulverised and abraded by friction.

In the able report of the Bastenne and Gaujac Bitumen Company, drawn up by Messrs. Goldsmid and Russel, these gentlemen have made an interesting comparison between the properties of mineral tar and vegetable tar: the bitumen composed of the latter substance, including various modifications extracted from coal and gas, have, so far as they were able to ascertain, entirely failed. This bitumen, owing to the qualities and defects of vegetable tar, becomes soft at 115° of Fahrenheit's scale, and is brittle at the freezing point; while the bitumen into which mineral enters will sustain 170° of heat without injury. In the course of the winter, 1837-38, when the cold was at 14½° below zero C., the bitumen of Bastenne and Gaujac, with which one side of the Pont Neuf at Paris is paved, was not at all impaired, and would, apparently, have resisted any degree of cold; while that in some part of the Boulevard, which was composed of vegetable tar, cracked and opened in white fissures. The French Government, instructed by these experiments, has required, when any of the vegetable bitumens are laid, that the pavement should be an inch and a quarter thick; whereas, where the bitumen composed of mineral tar is used, a thickness of three-quarters of an inch is deemed sufficient. The pavement of the bonding warehouses at Bordeaux has been laid upwards of 15 years by the Bastenne Company, and is now in a condtion as perfect as when first formed. The reservoirs constructed to contain the waters of the Seine, at Batignolles, near Paris, have been mounted 6 years, and notwithstanding the intense cold of the winter of 1837, which froze the whole of their contents into one solid mass, and the perpetual water pressure to which they are exposed, they have not betrayed the slightest imperfection in any point. The repairs done to the ancient fortifications at Bayonne, have answered so well, that the Government many years ago entered into a very large contract with the company for additional works, while the whole of the arches of St. Germain and St. Cloud railways, and the pavements and floorings necessary for these works, have been laid with Bastenne bitumen.

The mineral tar in the mines of Bastenne and Gaujac, is easily separated from the earthy matter with which it is naturally mixed, by the process of boiling, and is then transported in barrels to Paris or London, being laid down in the latter place to the

Digitized by Google

company at 17*l.* per ton, in virtue of a monopoly of the article purchased by the company at a sum, it is said, of 8000*l.*

Mr. Harvey, the superintendent of the Bastenne Company, was good enough to supply me with various samples of mineral tar, bitumen, and asphaltic rock for analysis. The tar of Bastenne is an exceedingly viscid mass, without any earthy impurity. It has the consistence of bakers' dough at 60° of Fahrenheit; at 80° it yields to the slightest pressure of the finger; at 150° it resembles a soft extract; and at 212° it has the fluidity of molasses. It is admirably adapted to give plasticity to the calcareous asphalts.

A specimen of Egyptian asphalt which he brought me, gave, by analysis, the very same composition as the Val de Travers, namely, 80 per cent. of pure carbonate of lime, and 20 of bitumen. A specimen of mastic prepared in France was found to consist, in 100 parts, of 29 of bitumen, 52 of carbonate of lime, and 19 of siliceous sand. A portion of stone called the natural Bastenne rock afforded me 80 parts of gritty siliceous matter and 20 of thick tar. The Trinidad bitumen contains a considerable portion of foreign earthy matter; one specimen yielded me 25 per cent. of siliceous sand; a second, 28; a third, 20; and a fourth, 30: the remainder was pure pitch. One specimen of Egyptian bitumen, specific gravity 1·2, was found to be perfectly pure, for it dissolved in oil of turpentine without leaving any appreciable residuum.

Robinson's Parisian Bitumen Company use a mastic made with the pitch obtained from boiling coal tar mixed with chalk. Portions laid down by this company at Knightsbridge and at Brighton are said to have gone to pieces. The pavement laid down by them in Oxford Street, next Charles Street, has been taken up. Claridge's Company have laid down their mastic under the archway of the Horse-Guards, and in the carriage entrance at the Ordnance Office: the latter has cracked at the junction with the old pavement of Yorkshire curb-stone. The foot pavement laid down by Claridge's Company at Whitehall has stood well. The Bastenne Company has exhibited the best specimen of asphalt pavement in Oxford Street; they have laid down an excellent piece of foot-pavement near Northumberland House; a piece 40 feet by 7, on Blackfriars' Bridge; they have made a substantial job in paving 830 superficial feet in front of the guard-room at Woolwich, which, though much traversed by foot-passengers, and beat by the guard in grounding arms, remains sound; lastly, the floor of the stalls belonging to the cavalry barracks of the Blues at Knightsbridge is probably the best example of asphaltic pavement laid down in this country, as it has received no injury from the beating of the horses' feet.

As the specific gravity of properly made mastic is nearly double that of water, a cubic foot of it will weigh from 125 to 130 lbs.; and a square foot, three quarters of an inch thick, will weigh very nearly 8 pounds. A ton of it therefore will cover 280 square feet. The prices at which the Bastenne Bitumen Company sell their products are as follows:—

Pure Mineral tar, 24*l.* per ton, or 28*s.* per cwt.
Mastic, 8*l.* 8*s.* per ton, or 10*s.* per cwt.

		Side Pavement.	Roofs and Terraces.
From 50	to 100 feet,	1*s.* 3*d.* per foot.	- 1*s.* 6*d.* per foot.
100	250	1*s.* 1*d.* - -	- 1*s.* 4*d.*
250	500	11*d.* - -	- 1*s.* 1*d.*
500	750	10*d.* - -	- 1*s.* 0*d.*
750	1000	9*d.* - -	- 11*d.*
1000	2000	8*d.* - -	- 10*d.*
2000	5000	7*d.* - -	- 9*d.*

Where the work exceeds 5000 feet, contracts may be entered into. For filling up joints of brickwork, &c. 1*d.* to 1½*d.* per foot run, according to quantity.

These prices are calculated for half an inch thickness, at which rate a ton will cover 420 square feet.

As the Val de Travers Company engage to lay down their rich asphaltic rock in London at 5*l.* per ton, and as a mineral tar equal to that of Seissel may probably be had in England at one fourth of the price of that foreign article, they may afford to lay their mastic three quarters of an inch thick per the thousand feet, including a substratum of concrete, at a rate of fivepence a square foot instead of fifteenpence, being the rate charged under that condition by the Bastenne Company.—*Ure.*

It has been thought advisable to preserve these remarks on bitumen, although most of the trials which have been made in this country can only be regarded as failures. Under the combined influences of sunshine, frost, and rain, it undergoes a rapid disintegration. It may be that the proper proportions of the respective

Digitized by Google

ingredients may not have been maintained, and that further trials are advisable. At present, although bitumen is employed, and with seeming advantage as a cement between paving stones, there is no extension of its application in the formation of foot pavement as recommended.

BITUMINOUS COAL. Coal rich in bituminous matter. Pitch or caking coal, cherry coal, splint coal, cannel coal, cooking coal, and some others, are varieties of bituminous coal. See COAL.

BIXINE and BIXEINE. Two conditions of the colouring matter of Arnatto, according to Preisser. See ARNATTO.

BLACK AMBER. Pitch coal is so called by the amber diggers of Prussia, and it is manufactured by them into jet-like ornaments.

BLACK BAND. A variety of the carbonates of iron, to which attention was first called by Mr. Mushet, at the commencement of the present century. The iron manufacture of Scotland owes its present important position to the discovery of the value of the black band ironstone. This ore of iron is also found in several parts of the coal basin of South Wales, and in the north of Ireland. The chemical composition of the black band iron ores will be given in connection with that of other minerals of the same class. See IRON ORES.

BLACK CHALK. A kind of clay containing a large amount of carbon. It is found in Carnarvonshire and in the Island of Islay.

BLACK COAL. Slate coal, cannel coal, and foliated coal, were so called by Jameson and other mineralogists of his day.

BLACK COBALT OCHRE. See COBALT EARTHY.

BLACK COPPER. An impure black oxide of copper. See COPPER.

BLACK DYE. (*Teinte noire*, Fr.; *Schwartze Farbe*, Germ.) Textile fabrics are dyed by various processes, according to the quality of the black required, and the kind of stuff on which the dye is to be produced.

The following processes for dying woollen stuff will be found to produce excellent results. For 1 cwt. of cloth previously dyed blue: — There is put into a boiler of middle size, 18 lbs. of logwood, with the same quantity of Aleppo galls, the whole being enclosed in a bag; this is boiled in a sufficient quantity of water for 12 hours: one-third of this decoction is transferred into another boiler with 2 pounds of verdigris; and the stuff is passed through this solution, stirring it continually during two hours, taking care to keep the bath very hot without boiling. The stuff is then lifted out, another third of the bath is added to the boiler, along with 8 pounds of sulphate of iron or green vitriol. The fire is to be lowered while the sulphate dissolves, and the bath is allowed to cool for half an hour, after which the stuff is introduced, and well moved about for an hour, and then it is taken out to air. Lastly, the remaining third of the bath is added to the other two, taking care to squeeze the bag well. 18 or 22lbs. of sumach are thrown in; the whole is just brought to a boil, and then refreshed with a little cold water; 2 pounds more of sulphate of iron are added, after which the stuff is turned through for an hour. It is next washed, aired, and put again into the bath, stirring it continually for an hour. After this, it is carried to the river, washed well, and then fulled. Whenever the water runs off clear, a bath is prepared with weld, which is made to boil for an instant; and after refreshing the bath, the stuff is turned in to soften, and to render the black more fast. In this manner, a very beautiful black is obtained, without rendering the cloth too harsh.

Commonly, more simple processes are employed. Thus the blue cloth is simply turned through a bath of gall-nuts, where it is boiled for two hours. It is next passed through a bath of logwood and sulphate of iron for two hours, without boiling, after which it is washed and fulled. But in all cases the cloth, after passing through the blue vat, should be thoroughly washed, because the least remains of its alkalinity would injure the tone to be given in the black copper.

Hellot found that the dyeing might be performed in the following manner: — For 20 yards of dark blue cloth a bath is made of 2 lbs. of fustic (*Morus tinctoria*), 4½ lbs. of logwood, and 11 lbs. sumach. After boiling the cloth in it for three hours it is lifted out, 11 lbs. of sulphate of iron are thrown into the boiler, and the cloth is then passed through it during two hours. It is now aired, and put again in the bath for an hour. It is, lastly, washed and scoured. The black is less velvety than that by the preceding process. Experience convinced him that the maddering prescribed in the ancient regulations only gives a reddish cast to the black, which is obtained finer and more velvety without madder.

According to Lewis, the proportions which the English dyers most generally adopt are, for 112 lbs. of woollen cloth, previously dyed of a dark blue, about 5 lbs. of sulphate of iron, as much gall-nuts, and 30 lbs. of logwood. They begin by galling the

Digitized by Google

cloth; they then pass it through the decoction of logwood to which the sulphate of iron has been added.

When the cloth is completely dyed, it is washed in the river, and passed through the fulling-mill till the water runs off clear and colourless. Some persons recommend, for fine cloths, to full them with soap water. This operation requires an expert workman, who can free the cloth thoroughly from the soap. Several recommend, at its coming from the fulling, to pass the cloth through a bath of weld, with the view of giving softness and solidity to the black. Lewis says, that passing the cloth through weld, after it has been treated with soap, is absolutely useless, although it may be beneficial when this operation has been neglected.

The following German process is cheap and good. 100 lbs. of cloth or wool are put into the copper with sufficient water and 15 lbs. of Salzburgh vitriol (potash-sulphate of iron) and 5 lbs. of argol, heating the bath gradually to boiling, while the goods are well worked about for two hours, taking them out, and laying them in a cool place for twenty-four hours. They are then to be put in a lukewarm bath of from 25 to 30 lbs. of logwood, and 10 lbs. of fustic, and to be worked therein while it is made to boil during two hours. The goods are now removed, and there is put into the copper 1¼ lbs. of verdigris dissolved in vinegar; the goods are restored into the improved bath, and turned in it for half an hour, after which they are rinsed and dried.

The process for dyeing merinos black is, for 100 lbs. of them to put 10 lbs. of copperas into the bath of pure water, and to work therein for a quarter of an hour, as soon as it is tepid, one-third of the goods; then to replace that portion by the second, and after another quarter of an hour, to put in the last third. Each portion is to be laid aside to air in the cold. The bath being next heated to 140° F., the merinos are to be treated as above piecemeal; but the third time it is to be passed through the bath at a boiling heat. Being now well mordanted, the goods are laid aside to air till the following day. The copper being charged with water, 50 lbs. of ground logwood, and 2 lbs. of argol, and heated, the goods are to be passed through, while boiling, for half an hour. They are then rinsed.

Different operations may be distinguished in dying *silk* black; the boiling of the silk,—its galling,—the preparation of the bath,—the operation of dyeing,—the softening of the black.

Silk naturally contains a substance called gum, which gives it the stiffness and elasticity peculiar to it in its native state; but this adds nothing to the strength of the silk, which is then styled raw; it rather renders it, indeed, more apt to wear out by the stiffness which it communicates; and although raw silk more readily takes a black colour, yet the black is not so perfect in intensity, nor does it so well resist the reagents capable of dissolving the colouring particles, as silk which is scoured or deprived of its gum.

To cleanse silk intended for black, it is usually boiled four or five hours with one-fifth of its weight of white soap, after which it is carefully beetled and washed.

For the galling, nut-galls equal nearly to three-fourths of the weight of the silk are boiled during three or four hours; but on account of the price of Aleppo galls, more or less of the white gall-nuts, or of even an inferior kind called galon, berry or apple galls, are used. The proportion commonly employed at Paris is two parts of Aleppo galls to from eight to ten parts of galon. After the boiling, the galls are allowed to settle for about two hours. The silk is then plunged into the bath, and left in it from twelve to thirty-six hours, after which it is taken out and washed in the river.

Silk is capable of combining with quantities, more or less considerable, of the astringent principle; whence results a considerable increase of weight, not only from the weight of the astringent principle, but also from that of the colouring particles, which subsequently fix themselves in proportion to the quantity of the astringent principle which had entered into combination. Consequently, the processes are varied according to the degree of weight which it is wished to communicate to the silk; a circumstance requiring some illustration.

The commerce of silk goods is carried on in two ways: they are sold either by the weight, or by the surface, that is, by measure. Thus the trade of Tours was formerly distinguished from that of Lyons; the silks of the former being sold by weight, those of the latter by measure. It was therefore their interest to surcharge the weight at Tours, and, on the contrary, to be sparing of the dying ingredients at Lyons; whence came the distinction of light black and heavy black. At present, both methods of dyeing are practised at Lyons, the two modes of sale having been adopted there.

Silk loses nearly a fourth of its weight by a thorough boiling, and it resumes, in the light black dye, one half of this loss; but in the heavy black dye, it takes sometimes upwards of a fifth more than its primitive weight—a surcharge injurious to the beauty of the black and the durability of the stuff. The surcharged kind is denominated English black, because it is pretended that it was practised in England. Since silk

Digitized by Google

dyed with a great surcharge has not a beautiful black, it is usually destined for weft, and is blended with a warp dyed of a fine black.

The peculirity of the process for obtaining the heavy black consists in leaving the silk longer in the gall liquor, in repeating the galling, in passing the silk a greater number of times through the dye, and even letting it lie in it for some time. The first galling is usually made with galls which have served for a preceding operation, and fresh gall-nuts are employed for the second. But these methods would not be sufficient for giving a great surcharge, such as is found in what is called the English black. To give it this weight, the silk is galled without being ungummed; and, on coming out of the galls, it is rendered supple by being worked on the jack and pin.

The silk dyers keep a black vat, and its very complex composition varies in different dye-houses. These vats are commonly established for many years; and when their black dye is exhausted it is renovated by what is called in France a *brevet*. When the deposit which has accumulated in it is too great, it is taken out, so that at the end of a certain time nothing remains of the several ingredients which composed the primitive bath, but which are not employed in the brevet.

For the dyeing of raw silk black, it is "galled" cold, with the bath of galls which has already served for the black of boiled silk. For this purpose, silk, in its native yellow colour, is made choice of. It should be remarked, that when it is desired to preserve a portion of the gum of the silk, which is afterwards made flexible, the galling is given with the *hot* bath of gall-nuts in the ordinary manner. But here, where the whole gum of the silk, and its concomitant elasticity, are to be preserved, the galling is made *cold*. If the infusion of galls be weak, the silk is left in it for several days.

Silk thus prepared and washed takes very easily the black dye, and the rinsing in a little water, to which sulphate of iron may be added, is sufficient. The dye is made cold; but, according to the greater or less strength of the rinsings, it requires more or less time. Occasionally three or four days are necessary; after which it is washed, it is beetled once or twice, and it is then dried without wringing, to avoid softening.

Any of these processes will produce a black without the goods being previously dyed blue, but generally when such common blacks, as they are technically termed, are dyed, more of the dye drugs are required, and also a little modification in the operations. Sometimes they are "bottomed" or "rooted," by first working them in a decoction of walnut-husks, and then dyed as above;—or, a good black may be dyed without any previous rooting, by working 1 cwt. of the stuff, for an hour, at a heat of 190°, in 6 lbs. of camwood: 6 lbs. of copperas are then added, and the stuff worked for another hour; the fire is then withdrawn from the boiler, and the stuff allowed to remain in the liquor for 10 or 12 hours. It is washed from this, and worked in a second bath with 60 lbs. of logwood for an hour and a half, then add 3 lbs. of copperas, and after another hour's working, it is washed.

Bichromate of potash is also used for dying blacks upon wool. A very good colour may be dyed direct by working, for 2 hours, 1 cwt. of the stuff in a solution of 5 lbs. of bichromate, 4 lbs. of alum, and 3 lbs. of fustic, then exposing it for an hour and washing well. It is again wrought for 2 hours in a second bath, made up with 45 lbs. of logwood, 3 lbs. of barwood or camwood, and 3 lbs. of fustic; then adding 3 lbs. of copperas, and after half an hour's longer working, the dye is finished. A much cheaper blue black than that produced by previously dyeing the stuff in the indigo vat, is obtained by using a Prussian blue, then proceeding as directed above.

Raw silk may be more quickly dyed by shaking it round the rods in the cold bath after the galling, airing it, and repeating these manipulations several times, after which it is washed and dried.

Macquer describes a more simple process for the black by which velvet is dyed at Genoa: and he says that this process, rendered still simpler, has had complete success at Tours. The following is his description.

For 1 cwt. (50 kilogrammes) silk, 22 lbs. (11 kilogrammes) of Aleppo galls, in powder, are boiled for an hour in a sufficient quantity of water. The bath is allowed to settle till the galls have fallen to the bottom of the boiler, from which they are withdrawn; after which 32 lbs. of copperas are introduced, and 22 lbs. of country gum, put into a kind of two-handled colander, pierced everywhere with holes. This kettle is suspended by two rods in the boiler, so as not to reach the bottom. The gum is left to dissolve for about an hour, stirring it from time to time. If, after this time, some gum remains in the kettle, it is a proof that the bath, which contains two hogsheads, has taken as much of it as is necessary. If, on the contrary, the whole gum is dissolved, from 1 to 4 lbs. more may be added. This colander is left constantly suspended in the boiler, from which it is removed only when the dyeing is going on;

Digitized by Google

and afterwards it is replaced. During all these operations the boiler must be kept hot, but without boiling. The galling of the silk is performed with one-third of Aleppo galls. The silk is left in it for six hours the first time, then for twelve hours. The rest, *secundum artem*.

Lewis states that he has repeated this process in the small way; and that, by adding sulphate of iron progressively, and repeating the immersion of the silk a great number of times, he eventually obtained a fine black.

Astringents differ from one another as to the quantity of the principle which enters into combination with the oxide of iron. Hence, the proportion of the sulphate, or of any other salt of iron, and that of the astringents, should vary according to the astringents made use of, and according to their respective quantities. Gall-nut is the substance which contains most of the astringent principle; sumach, which seems second to it in this respect, throws down (decomposes), however, only half as much sulphate of iron.

The most suitable proportion of sulphate of iron appears to be that which corresponds to the quantity of the astringent matter, so that the whole iron precipitable by the astringent may be thrown down, and the whole astringent principle may be taken up in combination with the iron. As it is not possible, however, to arrive at such precision, it is better that the sulphate of iron should predominate, because the astringent, when in excess, counteracts the precipitation of the black colouring particles, and has the property of even dissolving them.

This action of the astringent is such that, if a pattern of black cloth be boiled with gall-nuts, it is reducible to grey. An observation of Lewis may thence be explained. If cloth be turned several times through the colouring bath, after it has taken a good black colour, instead of obtaining more body, it is weakened, and becomes brownish. Too considerable a quantity of the ingredients produces the same effect; to which the sulphuric acid, set at liberty by the precipitation of the oxide of iron, contributes.

It is merely the highly oxidised sulphate which is decomposed by the astringent; whence it appears that the sulphate will produce a different effect according to its state of oxidisement, and call for other proportions. Some advise, therefore, to follow the method of Proust, employing it in the oxidised state; but in this case it is only partially decomposed, and another part is brought, by the action of the astringent, into the lower degree of oxidisement.

The particles precipitated by the mixture of an astringent and sulphate of iron have not at first a deep colour; but they pass to a black by contact of air while they are moist.

Black dye is only a very condensed colour, and it assumes more intensity from the mixture of different colours likewise deep. It is for this reason advantageous to unite several astringents, each combination of which produces a different shade. But blue appears the colour most conducive to this effect, and it corrects the tendency to dun, which is remarked in the black produced on stuffs by the other astringents.

On this property is founded the practice of giving a blue ground to black cloths, which acquire more beauty and solidity the deeper the blue. Another advantage of this practice is to diminish the quantity of sulphuric acid which is necessarily disengaged by the precipitation of the black particles, and which would not only counteract their fixation, but would further weaken the stuff, and give it harshness. For common stuffs, a portion of the effect of the blue ground is produced by the rooting.

The mixture of logwood with astringents contributes to the beauty of the black in a twofold way. It produces molecules of a hue different from what the astringents do, and particularly blue molecules, with the acetate of copper, commonly employed in the black dyes; which appears to be more useful the more acetate the verdigris made use of contains.

The boil of weld by which the dye of black cloth is frequently finished, may also contribute to its beauty, by the shade peculiar to its combination. It has, moreover, the advantage of giving softness to the stuffs.

The processes that are employed for wool yield, according to the observation of Lewis, only a rusty black to silk; and cotton is hardly dyed by the processes proper for wool and silk. Let us endeavour to ascertain the conditions which these three varieties of dyeing demand.

Wool has a great tendency to combine with colouring substances; but its physical nature requires its combinations to be made in general at a high temperature. The combination of the black molecules may therefore be directly effected in a bath, in proportion as they form; and, if the operation be prolonged by subdividing it, it is only with the view of changing the necessary oxidisement of the sulphate and augmenting that of the colouring particles themselves.

Silk has not the same disposition to unite with the black particles. It seems to be

Digitized by Google

assisted by the agency of the tannin, with which it is previously impregnated, especially after it has been scoured. A very deep black may be obtained upon 100 lbs. of silk, by working it for two hours in a solution of 20 lbs. of copperas and 3 pints of nitrate of iron. Wash from this thoroughly, and then wash for two hours more in a decoction of 100 lbs. of logwood and 20 lbs. of fustic. Lift up, and add to the bath a solution of 3 lbs. of copperas, and work half an hour longer, and wash. A beautiful rich blue black is produced by dyeing the silk a deep royal blue, then working for an hour in a solution of copperas (2 ounces to the pound of silk), washing from this, and working in a bath of logwood, using half a pound to each pound of silk, and adding, after an hour's working, a few ounces of copperas; working half an hour longer, and finishing.

Cotton has no affinity for the black dye, and has always to be impregnated or combined with astringent substances, in order to produce the dye. A good deep black will be imparted to 100 lbs. of cotton by steeping it in a decoction of 30 lbs. of sumach, at a boiling heat, and allowing it to stand till perfectly cold; then passing it through lime water, and, immediately after this, working for an hour in a solution of 20 lbs. of copperas. After this, expose for an hour to the air; then pass through lime water again, and wash and work for an hour in a bath of 30 lbs. of logwood and 10 lbs. of fustic; lift, and add 2 lbs. of copperas, and work 30 minutes longer, and finish.

BLACK FLUX. A mixture of charcoal and carbonate of potash, obtained by calcining bitartrate of potash. Generally, the crude tartar of commerce is used.

BLACK HÆMATITE. An ore of MANGANESE, (*which see*).

BLACKING FOR SHOES. (*Cirage des bottes*, Fr.; *Schuhschwärze*, Germ.) Blacking consists of a black colouring matter, generally bone black, and substances that acquire a gloss by friction, such as sugar and oil. The usual method is to mix the bone black with sperm oil; sugar, or molasses, with a little vinegar, is then well stirred in, and strong sulphuric acid is added gradually. The acid produces sulphate of lime and acid phosphate of lime, which is soluble: a tenacious paste is formed by these ingredients, which can be smoothly spread; the oil serving to render the leather pliable. This forms a liquid blacking. Paste blacking contains less vinegar. In Germany, according to Liebig, blacking is made by mixing bone black with half its weight of molasses, and one eighth of its weight of hydrochloric acid, and one-fourth of its weight of strong sulphuric acid, mixing with water, to form an unctuous paste. The following method for making liquid and paste blacking is given by William Bryant and Edward James: 18 ounces of caoutchouc are to be dissolved in about 9 lbs. of hot rape oil. To this solution 60 lbs. of fine ivory black and 45 lbs. of molasses are to be added, along with 1 lb. of finely ground gum arabic, previously dissolved in 20 gallons of vinegar of strength No. 24. These mixed ingredients are to be finely triturated in a paint mill till the mixture becomes perfectly smooth. To this varnish 12 lbs. of sulphuric acid are to be now added in small successive quantities, with powerful stirring for half an hour. The blacking thus compounded is allowed to stand for 14 days, it being stirred half an hour daily; at the end of which time 3 lbs. of finely ground gum arabic are added; after which the stirring is repeated half an hour every day for fourteen days longer, when the liquid blacking is ready for use. In making the paste blacking, the patentees prescribe the above quantity of india-rubber oil, ivory black, molasses, and gum arabic, the latter being dissolved in only 12 lbs of vinegar. These ingredients are to be well mixed and then ground together in a mill till they form a perfectly smooth paste. To this paste 12 lbs. of sulphuric acid are to be added in small quantities at a time, with powerful stirring, which is to be continued for half an hour after the last portion of the acid has been introduced. This paste will be found fit for use in about seven days.

Of blacking, in 1864, we *exported* as follows:—British Possessions in South Africa, 2,047*l.*; Bombay and Sinde and Madras, 1,931*l.*; Bengal and Pegu, Singapore, and Ceylon, 1,381*l.*; Australia, 11,276*l.*; British West India Islands, and British Guiana, 2,714*l.*; other countries, 5,354*l.*; making a total of 24,721*l.*

BLACK JACK. The miner's name for blende, or sulphide of zinc. See ZINC.

BLACK-LEAD PENCILS. See PENCIL MANUFACTURE.

BLACK LEAD. The common name of PLUMBAGO or GRAPHITE (*which see.*)

BLACK TIN. The miner's name for tin ore ready for the smelter.

BLACK WADD. One of the ores of manganese. See MANGANESE.

BLADDER. (*Vessie*, Fr.; *Blase*, Germ.) A bag or sack, in animals, which serves as the receptacle of some secreted fluid. Bladders are chiefly employed for securing jars, bottles, &c. In addition to the very large quantities which are obtained in this country, we *imported*, in 1863, 2,051,680; and in 1864, 1,653,548.

BLANKETS. (*Blanchet*, Fr.) A cover for a bed made of coarse wool loosely

Digitized by Google

woven. Among printers the woollen cloth which is placed between the tympans is called a *blanket*. See WOOLLEN MANUFACTURES.

BLAST. The current of air driven into a furnace; it may be either cold or hot air. See HOT BLAST.

BLAST FURNACE. A furnace into which air is forcibly blown. See IRON-METALLURGY.

BLAST HOLES. *A mining term.* The holes through which the water enters the bottom of a pump in the mines.

BLASTING. The process of rending rocks by the use of some explosive compound, as gunpowder. See MINING.

BLEACHING (*Blanchement*, Fr.; *Bleichen*, Germ.) is the process by which the textile filaments, cotton, flax, hemp, wool, silk, and the cloths made of them, as well as various vegetable and animal substances, are deprived of their natural colour, and rendered nearly or altogether white. The term bleaching comes from the French verb *blanchir*, to whiten.

In ancient times bleaching, washing, and fulling were not distinctly separated; they were all practised. We read in the Scriptures of "fine linen, white and clean," and in Greek authors, of "raw linen," of which towels were made, as well as of "shining fine linen," for the same purpose, thus at once making the distinction.* The pure white was apparently not so common as with us. A pure surface was, however, needful, in order to produce good colours, for which we are bound to give the ancients credit, as we know they were acquainted with them as pigments, and are not, therefore, to be suspected of being unable to distinguish good from bad when transferred to textile fabrics. As their words for white and for colour are plain enough in general, we must conclude that they had the power of obtaining both fine whites and finely-dyed cloth; handkerchiefs were tied about the head in various ways, as now in Lancashire, white and coloured. The Babylonians wore white cloaks.† By their method of washing, the discovery of bleaching was inevitable, the cloth being washed several times and dried in the sun. But it was not left in the state of an accident only; the word *insolation* shows that the effects of the sun had been observed and classified, and this is stated to have been the chief method, as it is now, of bleaching wax. Egypt and the East seem to have been the teachers in bleaching. From Egypt were obtained alkalis, and soda mixed with lime. Both lime and alkalis were used in the process. Potash, or the ashes of plants, was also used, and soap-plants, in all probability of various kinds, as it is not easy to decide on one. The *Saponaria officinalis*, soap-wort, is still used, and the wake-robin or cuckowpint, *Arum maculatum;* the *Gypsophila Struthium* was considered by Linnæus to be the ancient one, and is still called *Lanaria* in Italy. Nor do we require to suppose that this plant was first incinerated, as has been supposed, in the case of Borith, the fullers' soap of the Bible. Vegetable decoctions are still used in China to bleach silk, and in France even now; some have been patented within a few years in England, although little used. The Latin method of obtaining white cloth is very well preserved, and as they got their caustic soda from Egypt, it is probable that they got also their process; nor is it at all likely that Nicias of Megara invented fulling, as it was evidently well known before the existence of any well-founded Greek tradition. Pictures exist in Pompeii of men dancing the fullers' dance, or stamping cloth with their feet, as women now practise in Scotland. Moderate sized tubs were used: the clothes seem occasionally to have been taken up by the hand, in order that they might be well turned. They were then treated with ammoniacal liquors and soda. Urine was highly esteemed for the purpose. The fullers obtained it by placing vessels at the corners of the streets, which were removed when filled; this practice acting at the same time as a sanitary precaution. The same method of carefully collecting this fluid, or "old lant," as it is called, exists in the woollen districts of Lancashire and Yorkshire. A tax was laid on it by Vespasian, so that the fullers might not receive it without payment. The cloth was then sulphured, if it was intended to be white: this process was performed under a conical frame like a small tent, the cloth being spread round the frame, and a vessel of sulphur burned under it.‡ Potters' earth was then used according to circumstances. The fuller seems to have been a bleacher as well as domestic laundryman. He had, therefore, white as well as coloured dresses to deal with. For the first he used Sardinian potters' earth, which could not be employed for prints or such colours as easily changed (*versicolores*). For coloured cloth, sulphur was not used by the potters, but fine Cimolian earth. The potters' earth seems to have been used both before and after sulphuring, according to circumstances. This second process is allied partly to our mode of chalking white dresses, still somewhat in use; but more strongly allied to what is called dressing, stiffening, and finishing. Pliny says that the Umbrian earth was only used for polishing vestments, also that it

Digitized by Google

softened fine colours and gave lustre to those that were faded in sulphuring. This shows that they used sulphur in washing, and not merely in preparing for the bleaching process.* They then gave a finish of very fine clay, gypsum being used instead of clay in Greece, as amongst ourselves. If a nap was wanted, it was raised after sulphuring, by brushing, by carding, by the skin of a hedgehog, or by thistles and teasels. They seem to have got a fine nap on their woollen cloth, as garments of this kind once washed were considered less valuable, as would be the case with our broadcloth for outer dresses. Wool for under dresses could not have been injured by one washing, especially as the *fullones* seem in old Italy to have been more attentive than our washerwomen, and to have formed a college, or at least a guild. The washing was seldom done at home, except in large establishments, especially in the country. Whiteness was very much esteemed, and great pains taken to obtain it. Coloured cloth seems a later invention. This love of whiteness was so great, that those who were too poor to have their cloths fulled, rubbed them with a white fullers' earth, so as on holidays to appear clean and bright.

Clothes in ancient times required a good deal of washing, so much oil being used; alkalis alone could remove this, and people that used soft feather-beds, and pillows that sank under the weight of the head, would not be behind in having them also whitened. In India the mode was different from that used in the western world. The preparation for printing was a series of washings, beatings, and exposure to the sun, as well as wearing next the skin, and steeping in goats' and sheep's dung. Wearing next the skin was probably instead of the oiling process in Turkey red. Bleaching with boiled rice water was practised in India. In Jamaica the aloe was used, and in China a bean is employed: this is smaller than the Turkey bean; five parts are used to five of salt, six of flour, and twenty-five of water: this is for raw silk. The exact action of the vegetable method on the colouring matter is not well known; but it must not be iguored. The decompositions of fermentation and putrefaction have a great power of propagating themselves; we can, in fact, readily conceive the decomposition of gums by such means, provided they are not resinous matters, consisting chiefly of carbon and hydrogen. Mucilaginous plants are even now in some places used, and have been recommended also in the most modern times.† It is, therefore, not easy to see why so much difficulty has been raised amongst chemical historians as to the use of plants in washing and bleaching. Vegetable products, such as oatmeal, &c., have powerful detergent qualities, and leave the skin exceedingly soft. In general we may conclude that these vegetable infusions and alkalis were the means of bleaching in ancient times, the influence of the sun being also employed. At present, alkalis are more generally used. Washing with alkalis is really the most important part of the process. The soaps of the ancients were also vegetable or alkaline, or both; they were a σμῆγμα, but not a true soap, in general at least.—*Paulus Ægineta*, Notes by Adams.

Until modern times no improvements of great importance took place affecting the principles of bleaching; and even now the only modern changes consist in the introduction of chlorine and machinery, to which may be added the greater abundance of soap. In the last century, Holland obtained the best name for bleaching. The process passed then to Ireland and Scotland, and thence into England. It was even customary to send goods from this country to be bleached in Holland. The first attempt to vie with Holland was made in Scotland in 1749.

We find in the patent lists many crude efforts made to improve the art. Alkalis and acids are recommended in various forms, and such a variety of substances as tartar, saltpetre, sal ammoniac, marl, loam, clay, mud, chalk, fullers' earth, oyster shells, soot, turf, and ashes, with a great variety of washing machines.

The value of the plan in Holland was ascribed to the ashes of Muscovy (Russian potash) and the sea water; but it is evident, from the description, that it was not sea, but very pure fresh water which was used. The Dutch process is thus described:—"When a piece of linen is to be bleached, it is in the first place steeped in a lixivium, or lye, where other cloth has been trod; afterwards it is trod in a new lye of ashes poured upon it boiling hot. This is boiled in large copper caldrons, and is never poured upon the cloth till it is as clear as wine. The linen is left eight days in this lye, after which it is washed and pressed in this manner:—They empty some buckets of butter-milk into wooden vessels fixed in the ground; then they throw in a piece of linen, which three men tread with their feet as much as possible. Afterwards they pour in more butter-milk, and then another piece of cloth, proceeding thus alternately till the vessels are nearly filled, when they lay planks over the linen, upon which they raise a large round piece of wood, or great stake, touching the lower side of a beam, between which and the stake they drive wedges to press the cloth. Six or seven days after they take the cloth out of these vessels, and if it be not white

* Nat. Hist. xxxv., 57, &c.

† See Globert's process.

Digitized by Google

enough, they steep it as we have described above. Afterwards it is washed and spread out upon the ground to bleach. It must be remarked that after every dipping the cloth is washed first with black soap, then with clear water, and after each of these operations it is wrung by means of a machine that turns by means of a wheel. .... The whitening grounds are cut with canals in some places, that there may be no trouble of fetching water from a distance. The cloth is watered with long narrow shovels made in shape of a scythe. The water of these canals comes from the dams, and it is that which contributes most to the lustre of the Dutch cloth. To prevent the water from becoming thick and muddy, they are extremely careful in cleaning these canals. The washing tubs are built with bricks, with two trap-doors or sluices for admitting or excluding the water according as it is necessary." — *Select Essays*, quoted by Parke.

The chief advantage here consists in the facility of obtaining soap, which in ancient times was either scarce or badly made. This improvement began to be more and more used from the time of its earliest introduction. Modern times have begun to exclude it to a great extent again, finding it so much cheaper to work with the alkali alone without combining it with fatty matter.

The process of bleaching then became a series of operations, consisting of, 1st, steeping in water for about three or four days, or in weak alkali for forty-eight hours. 2nd, boiling in an alkaline lye, or, in other words, *bucking* or bowking: in this operation the hot lye was poured on the cloth; it then ran through it, was drawn off by a tap below, and then pumped up again. 3rd, crofting, or exposure to sun and air on the grass. 4th, souring: this was done by the butter-milk; it lasted several weeks. These operations were repeated four or five times, or until the goods were pure. The whole lasted from March to September. The best months for crofting were found to be March, April, and May. It was not known that it was the acid of the butter-milk which acted; but when sulphuric acid became cheaper, Dr. Home applied it instead of butter-milk, and caused a great revolution in bleaching, as the souring could now be done in a day which before had occupied weeks, exposing the cloth to much danger of decay by decomposition or putrefaction. Great fear was expressed in the country lest the vitriol should burn the cloth, when Dr. Home stated that he had kept linen in acid of the required dilution for some months without having it injured. Berthollet also said that the acid made a better white.

But in 1784 Berthollet made known some investigations on chlorine, and in 1787 communicated them to the French Academy. By these investigations it was found that chlorine had the power of destroying colouring matters. The use of chlorine was brought to this country by the Duke of Gordon and Professor Copeland of Aberdeen, who then gave the process to be carried out by Messrs. Milnes, of the firm Gordon, Barron, and Co., of that place. In this discovery the theoretical portion is due, first, to Scheele, who discovered the chlorine; and, secondly, to Berthollet, who discovered the peculiar property. The practical mode of effecting the object is the part which we claim; but it consists of such a long series of expensive trials and ingenious contrivances, that it will take a much longer time to describe them than to give the first idea only. As the invention was at first applied only to cotton, which at that period was rising into importance, we shall begin the description of modern bleaching with the mode adopted for that material.

James Watt at the date given was in intimate communication with Berthollet, and did not rest until he had made the process successful at the bleach-field of Macgregor, near Glasgow, requesting the results to be communicated to a meeting of manufacturers to be called together at Manchester;—so quick was Watt to see what would be for the permanent interest of a country, and so ready to act on it! Dr. Henry did much to make it known to the manufacturers about Manchester. This is one of the early instances of scientific men being directly applied to by manufacturers for assistance — an application seldom made unless under great difficulties.

The principal bleaching agents, besides alkalis and other matters mentioned, are chlorine, sulphurous acid, and the combined action of air and light. These are destroyers of colour. The chief agents for removing colours which do not require to be previously decomposed, are alkalis. The principal amount of the colouring materials are removed from the cloth by washing with alkalis: the last tint of whiteness is not removable by this means, and it is to this last tint that the word bleaching has been more definitely applied.

In 1798, Charles Tennant, of Glasgow, introduced chloride of lime, which is preferred above all other compounds to the present day as a means of applying chlorine.

The true theory of bleaching has not been entirely agreed upon, but there can be little doubt of the principal operations. It is known that oxygen deprives substances of colour; this may be performed by many high oxides; by nitric acid, manganic and chromic acids, chlorous acid, and even lower oxides which hold their oxygen lightly, as hypochlorous acid. The same effect may be produced by chlorine,

Digitized by Google

bromine, and iodine. It has been said that chlorine unites with the hydrogen of the water which is present, gives off oxygen, and so acts just as oxygen would. Davy found that it would not act in dry air, so that water was needful: but Dr. Wilson found that it would act, although slowly, in dry air, if exposed to the rays of the sun This might show that water is not necessary in order to supply oxygen, but only to allow the chlorine to be brought into thorough contact with the colouring matter. It has also been supposed that the chlorine removes the hydrogen, or, rather, simply takes its place by an act of substitution. Now, whether the chlorine or the liberated oxygen removes the hydrogen, the result will be the same — the destruction of the compound. Chlorine so readily performs these changes, that we should at once decide on calling it the active agent, were it not for the fact that oxygen acts so readily, even when chlorine is not present: for example, peroxide of hydrogen, as well as the oxides just mentioned, and ozone also, which has no chlorine to help it. It is, then, certain that oxidation bleaches; and it is certain that dehydration bleaches, if performed by chlorine, and that the sun aids it by its active rays. We know also that water aids it: water aids bleaching or oxidation by air, partly because it contains air in solution. It aids also the bleaching performed by solutions in contact with porous bodies, because these bodies have a power of condensing gases in their pores and of compelling combinations. The next question is, Does it aid the bleaching by chlorine in the same way, by assisting the union mechanically, or by decomposing water? Chlorine acts slowly, unless water be present. The theory, therefore, does not demand the decomposition of water, and the known powerful affinities of chlorine do not require to be supplemented by oxygen. But, in order to see exactly the state of the case, let us look at the action of chlorine in hypochlorites or in chloride of lime, and we find that it is a direct oxidation. We obtain by it peroxides of metals, and not chlorides. Here we seem to be taught directly by experiment, that bleaching by hypochlorites is an oxidation of the colouring matter. Bleaching by moist chlorine may therefore be looked on as the same; indeed, we oxidise by it; but in such cases we may obtain the base at the same time united to chlorine, giving another turn to the question, as Kane showed. The oxidation theory, therefore, seems to be sufficient when water is present. We are, however, finally to deal with dry chlorine in the sun; and in that case it is fair to conclude that it acts by direct combination with hydrogen or the colouring matter or both. We have, then, two modes of bleaching; but the usual mode in the air becomes by that explanation an oxidation, and the direct action of chlorine obtainable only with difficulty. When sulphurous acid is used, another phenomenon may be looked for, as we find a substance whose chief quality is that of deoxidising. The removal of oxygen also decomposes bodies, and sulphuretted hydrogen can scarcely be supposed to act in any other way. Sulphurous acid, when it decomposes sulphuretted hydrogen, really acts as an oxidising agent, and we can therefore imagine it as such in the bleaching process. Investigation has not told us if it enters into combination as SO^2, and, like oxygen, destroys colour, altering the compound by inserting itself.

We may fairly conclude that the processes by chlorine and sulphurous acid are performed in a manner as different as the mode in which a salt of ammonia acts on chlorine or an oxacid, or, in Dr. Wilson's general terms, "Specific differences may be expected to occur with all the gases named, as to their action on any one colouring matter, and with different colouring matters, as to their deportment with any one of the gases." — *Trans. R. S. E.*, 1848.

It has been attempted to introduce manganates, chromates, chlorates, chlorochromic acid, and sulphites, but without success, as bleaching agents.

Bleaching of Cotton.

Substances dealt with in Bleaching.—The object of bleaching is to separate from the textile fibre all the substances which may mask its intrinsic whiteness, or which, in the course of dyeing or printing, may produce injurious effects on the colours. The substances present in cotton goods, and to be treated in bleaching, are as follows:—

a. The resinous matter natural to the filaments.
b. The colouring matter of the plant.
c. The paste of the weaver.
d. A fatty matter.
e. A cupreous soap.
f. A calcareous soap.
g. The filth of the hands.
h. Iron rust, earthy matters, and dust.
i. The cotton fibre itself.
j. The carbonaceous matter caused by singeing.
k. The seed-vessels.

Digitized by Google

a. Cotton is covered with a resinous matter, which obstructs its absorption of moisture. This alone would prevent it receiving colour, and it is known that if this could be removed, some of the darker colours could be dyed without any bleaching, providing also the impurities arising from manipulation were absent, although the finest colours could not be produced in this manner on cotton in general. M. Bolly, however, has proposed the use of acetic acid, or of a sour bran liquor, as substances which are absorbed by the cotton and render it capable of absorbing colour or solutions. The matter which prevents the moistening has not been thoroughly examined. It is found to be soluble in alcohol and ether, and some of it in turpentine: it is therefore called a resinous, waxy, or fatty body. It is dissolved by alkalis, and thrown down by acids in strong solutions. The alcohol solution leaves thin yellowish scales, which may be dissolved in acid or even in much water. But information concerning it is indistinct. For a long time the process commenced by removing this resin by means of alkali. It is called scouring.

b. The whole colouring matter is not soluble in alkalis, but it becomes so after being altered by the action of chlorine, or by insolation or croft bleaching. It is not even capable of being bleached, or at least but slowly, unless it be previously acted on by alkalis. The amount of colour is much less with cotton than linen. The former is often so white naturally, that washing and bleaching might be dispensed with, were it not for the substances which, during its manufacture, come in contact with it, if the gum were removed which prevents the moistening. The alkaline solution from the raw linen, when precipitated by acids, throws down a nearly black resinous mass, and the total loss of weight is very great.

c. The weaver's dressing is composed chiefly of farinaceous, glutinous, or gelatinous substances, starch, flour, or size. They are usually allowed to become sour before using. They are all dissolved by water or alkaline solutions, including lime. When the dressing gets dry, the hand-weaver occasionally renders his warp-threads more pliant by rubbing some cheap kind of grease upon them. Hence it happens that the cloth which has not been completely freed from this fatty matter will not readily imbibe water in the different bleaching operations; and hence, in the subsequent processes, these greasy spots, under peculiar circumstances—somewhat like lithographic stones—strongly attract the aluminous and iron mordants, as well as the dyestuffs, and occasion stains which it is almost impossible to discharge. The acids act differently upon the fatty matters, and thence remarkable anomalies in bleaching take place. When oil is treated with the acetic or muriatic acid, or with aqueous chlorine, it evolves no gas, as it does with the sulphuric and nitric acids; but it puts these substances into a condition in which they cannot be dissolved by a strong boiling lye of caustic soda. Carbonic acid is said to have a similar action with oil.

d. Both cotton and linen contain a little fatty matter, which is removed in the same manner as the resinous. Some of it comes from the mode of treating the warp, which is occasionally greased for weaving. This prevents, like resinous matter, the thorough saturation by solutions which are not alkaline, and soap, soda, or potash must be used to remove it by solution. Lime makes an insoluble soap, and is therefore not suited to the operation. If, however, lime has been used, the insoluble soap may be removed by treating with carbonate of soda, which forms a carbonate of lime, and leaves the fat in combination with the alkali. The carbonate of lime is then removed by an acid. This is, however, an indirect method; and the mode universally used is to decompose the lime soap by an acid, and remove the lime, leaving the fat in the cloth; then to wash out the fat by an alkali, or by soap and alkali mixed, as is the custom almost everywhere. The soap used is in great measure a resinous one, for cheapness, and it is mixed with carbonate of soda.

e. When the hand-weavers' grease continues in contact for a night with the copper dents of his reed, a kind of cupreous soap is formed, which is sometimes very difficult to remove from the web. Lime-water does not dissolve it; but dilute sulphuric acid carries off the metallic oxide, and liberates the margaric acid, in a state ready to be acted on by alkalis.

f. When cloth is boiled with milk of lime, the grease which is uncombined unites with that alkaline earth, and forms a calcareous soap, pretty soluble in a great excess of lime-water, and still more so in caustic soda. But all fats and oils, as well as the soaps of copper and lime, cease to be soluble in alkaline lyes when they have remained a considerable time upon the goods, and have been in contact with acetic, carbonic, muriatic acids, or chlorine. These results have been verified by experiment.

g. Cotton goods are sometimes much soiled, from being sewed or tamboured with dirty hands; but they may easily be cleansed from this filth by hot water.

h. Any ferruginous or earthy matters which get attached to the goods in the course of bleaching are readily removable, if not allowed thoroughly to penetrate the cloth; but the fine ferruginous clay found in suspersion in water is very difficult to wash off,

Digitized by Google

and it probably cannot, by any means, be removed from printed goods without spoiling the colours.

i. In all these operations it is needful to consider the most important substance of all—the fibre. Each of the operations may weaken or destroy it, if managed unwisely. Caustic lime may be allowed to act for a long time on cloth without any injury, but if allowed to act on it with free access of air, it destroys it in a few hours. Neither can cloth stand the action of alkalis of any kind very long: if very strong, they rapidly destroy it. The same thing may, in a still stronger sense, be said of acids; and chloride of lime or bleaching powder acts in the same direction. Linen, although mechanically much stronger than cotton, has not an equal chemical resistance to decomposition. It has not, therefore, been possible to use chloride of lime so as entirely to complete the process of bleaching linen, but only to hasten it, the completion being still nearly in all cases made by crofting. The bleacher has found out these things by expensive experience, and every day shows the importance of guarding against the excessive action of any one of the bleaching agents. Goods are continually suffering from the desire of speed on the part of the trade, and especially of the buyer; nor is it easy to find them absolutely uninjured by the process of bleaching, although it seems possible to conduct the process so that no weakening will ensue. The precautions taken are such as cause the processes to appear very long and tedious. The boiling with lime is continued as long as it is safe; the cloth is then at once washed and scoured, so as to remove all the caustic earth from the fibre. The acid is not allowed to remain long, but is, within from two to four hours, washed out by machines which cause the cloth to be frequently and rapidly saturated with water; and when one of these processes is not enough, it is found better to return to it again than completely to finish it at once, to the danger of the fibre; in the same way as workmen, if they find it needful to put their hands into hot water, do it rapidly and for a short time, but bring them out to cool before they return to the charge. To dry the goods with even a very small amount of acid would infalliby render them rotten. When the chlorine has oxidised or otherwise acted on the colouring matter, so as to render it soluble, it is washed out with alkalis; but the whole may not be acted on by the first process, and a second may be needful. Again, as to crofting: one exposure may not be found enough; another washing and another crofting are then needed, and a third, and so on, according to the method employed and the nature of the material used.

The souring by vegetable substances or by fermentation may also injure the cloth, not by the amount of acid existing in the solution, but the decomposition which becomes communicated from the vegetable matter to the cloth, and so renders it weak and rotten. The same is peculiarly the case when putrefactive action is allowed to commence. This was often the case when the gluten of the paste was removed by fermentation. It has been said that the action of carbonic and acetic acid on the fats is a great objection to the fermentation process, as they are thought to render the fat insoluble, and produce an indelible mark.

Experiments undertaken for the purpose have shown that the strength of the fibre is not impaired by being boiled in milk of lime for two hours, at the ordinary pressure, provided it is not exposed at the same time to air; but bleachers consider that, practically, the goods are not injured by boiling with lime for sixteen hours at the strength of 40 lbs. to 100 gallons. It has also been proved that caustic soda of the specific gravity of 1030° does not hurt them, even boiled under the pressure of 140 lbs. to the square inch, or immersion for eight hours in chloride of lime solution containing 3 lbs. to 100 gallons, and afterwards in sulphuric acid of the specific gravity of 1067°, or eighteen hours at the specific gravity of 1035°.

j. The carbon left by the singeing is entirely removed, but it is not clear what becomes of it. It disappears in the alkaline solution, as no traces seem to exist after this action. Probably the blackness or darkness is not caused by any pure carbon, but by compounds soluble in alkalis. If any elementary carbon exist, it is carried away almost entirely, no doubt, by mechanical means.

k. The same method gets rid of the particles of pod which remain in the cotton, and after the first washing seem to stand out very prominently, swelling up into large dark spots. The alkali probably renders them soft, and allows them to mix readily with liquids, if not altogether actually dissolved.

General Process of Bleaching.—The process of bleaching, from what we have seen, resolves itself into treatment with alkalis and the action of chlorine or of light. In describing the operations, they seem to be very numerous; but, as explained, some require to be repeated gently, instead of being finished by one decisive operation, so so as not to injure the fibre; and some are intermediate operations, such as the frequent washings needed in passing from one process to the other. The alkaline solution in which the goods are boiled does not contain above 250 lbs. of carbonate of soda to 600 gallons, but nearly always less. Lime is, however, used much more frequently

Digitized by Google

than soda, which it will be seen is only employed in the second process, and the third, if there be one. It is less hurtful to the cloth, and is much cheaper than the alkalis.

The chloride of lime is used at ¼ Twaddle, or 1002·5. It is not considered so important now as formerly, and where 300 lbs. were formerly employed, 30 to 40 are now used. The goods are made nearly white by the alkalis. The chlorine gives only the last finish, and is sometimes used to whiten the ground on coloured goods. The whole process may be expressed thus:—Wash out the soluble matter; boil with lime to dissolve still more, and to make a fatty compound with the oily matter; wash out the lime by acids; wash out the fat with a soda soap; clear the white by chloride of lime.

The impurities in the cloth have a certain power of retaining colour upon them. Mud and dirt, as well as grease, gluten, and albuminous matters, have this property, and fatty soaps, such as lime compounds of fatty acids. The pure fibre, however, has no power of taking up solutions of such colouring matter as madder. When, therefore, it is desired to try the extent to which cloth has been bleached, it is dyed or boiled up with madder exactly as in the process of dyeing. It is then treated with soap, as the madder-dyed goods are treated, and if it comes out without a stain, or nearly pure white, the goods are ready. Dyers or calico-printers who dye printed goods are exceedingly particular as to the bleaching, the dyeing and printing having now approached to such exactness, that shades invisible to any eye not very much experienced are sufficient to diminish in a material degree the value of the cloth. Any inequality from irregularity of bleaching, which causes a similar irregularity of dyeing, is destructive to the character of the goods. Many patterns, too, have white grounds; these grounds it is the pride of a printer to have as white as snow. If delicate colours are to be printed, they will be deteriorated if the ground on which they are to be printed is not perfectly white.

The stains which come out upon maddered goods in consequence of defective bleaching are sometimes called *spangs*. Their origin is such as I have described above, as the following statements of facts will show. The weaver of calicoes receives frequently a fine warp so tender, from bad spinning, or bad staple in the cotton, that it will not bear the ordinary strain of the heddles, or friction of the shuttle and reed, and he is obliged to throw in as much weft as will compensate for the weakness or thinness of the warp, and make a good marketable cloth. He of course tries to gain his end at the least expense of time and labour. Hence, when his paste dressing becomes dry and stiff, he has recourse to such greasy lubricants as he can most cheaply procure, which are commonly either tallow, or butter in a rancid state, but the former, being the lowest priced, is preferred. Accordingly, the weaver, having heated a lump of iron, applies it to a piece of tallow held over the warp in the loom, and causes the melted fat to drop in patches upon the yarns, which he afterwards spreads more evenly by his brush. It is obvious, however, that the grease must be very irregularly applied in this way, and be particularly thick on certain spots. This irregularity seldom fails to appear when the goods are bleached or dyed by the common routine of work. Printed calicoes, examined by a skilful eye, will be often seen to be stained with large blotches, evidently occasioned by this vile practice of the weaver. The ordinary workmen call these *copper* stains, believing them to be communicated in the dyeing copper. Such stains on the cloth are extremely injurious in dyeing with the indigo vat.

Old Methods still in use.—As a specimen of the older processes, we shall give the following, adding afterwards a minute account of some of the plans adopted by the most successful bleachers. When grease stains do not exist, as happens with the better kind of muslins, or when goods were not required to be finely finished, the following has been adopted:—After singeing, 1. Boiling in water. 2. Scouring by the stocks or dash-wheel. 3. Bucking with lime. 4. The bleaching properly so called, viz., passing through chlorine or crofting. 5. Bucking or bowking with milk of lime. These two latter processes employed alternately several times, till the whole of the colouring matter is removed. 6. Souring. 7. Washing.

Another routine has been, 1. Cleansing out the weavers' dressing, by steeping the cloth for twelve hours in cold water, and then washing it at the stocks or dash-wheel. 2. Boiling in milk of lime, of a strength suited to the quality of the goods, but for a shorter time than with the soda lye; two short operations with the lime, with intermediate washing, being preferable to one of greater duration. 3 and 4. Two consecutive lyes of ten or twelve hours' boiling, with about 2 lbs. of soda crystals for 1 cwt. of cloth. 5. Exposure to the air for six or eight days, or the application of chloride of lime and then sulphuric acid. 6. A lye of caustic soda. 7. Exposure to the air for six or eight days, or chlorine and acid as above. 8. Caustic-soda lye as before. 9. Chlorine and the sour. 10. Rinsing in hot water, or scouring by the dash-wheel.

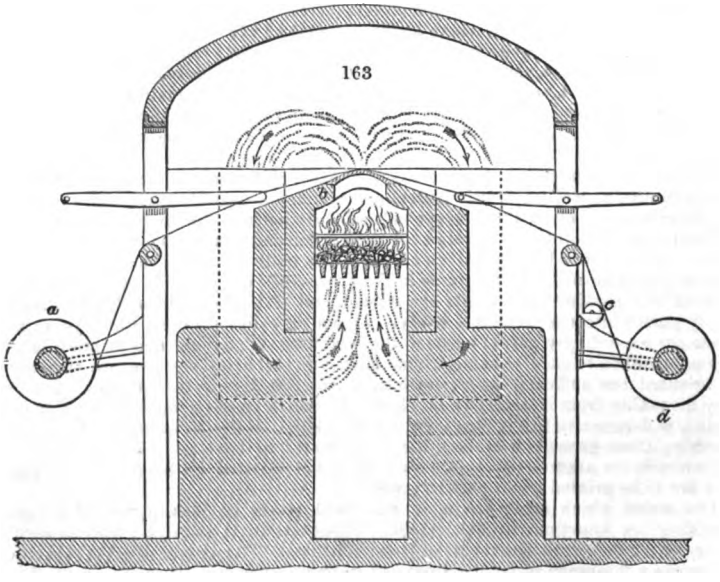
The Processes used in Bleaching. Singeing.—The singeing is performed by passing the cloth over a red-hot plate of iron o rcopper. The figure 163 shows this apparatus

163



as improved by Mr. Thom. At *a* there is a cylinder, with the cloth wound round it to be singed; it passes over the red-hot plate at *b*, becomes singed, passes over a small roller at *c*, which is partly immersed in water, and by this means has all the sparks extinguished; then is wound on to the roller *d*, when the process is finished. As the products of combustion from the singeing are sometimes very unpleasant, they are carried by this apparatus into the fire-place, where they are consumed. The arrows show the passage of these vapours from the surface of the cloth downwards into the hearth, and thence into the fire.

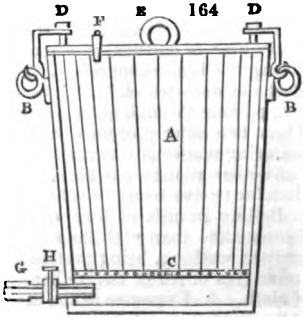
For goods to be finely printed both sides are singed; for market bleaching, one side. Sometimes, however, singeing is not at all desired.

The use of a line of gas jets instead of a red-hot plate, was introduced by Mr. Samuel Hall. It has not, however, found its way generally into bleach works: the plate is preferred. Gas jets are used necessarily in singeing threads. See SINGEING.

Shearing.—For fine printing, it is by some considered needful to shear the nap of the cloth instead of singeing it. The method is more expensive than singeing. Messrs. Mather and Platt have made a machine which will shear 60 to 80 yards per minute.

Bucking or *Bowking.*—This is the process of boiling goods. It is performed in alkaline liquids, generally lime, or soda, or both. The kier for bowking is a cylindrical iron vessel, the chief peculiarity of which is a method of preventing the cloth from being burnt on the bottom of the vessel, or allowed to dry on the vessel, or so to be pressed on the bottom as to prevent the boiling of the liquid in a uniform manner. This is done by simply having a false bottom to the kier, or a wooden perforated bottom, about eight or ten inches above the actual bottom.

164



The boiler, such as A, *fig.* 164, has a stopcock, H G, at bottom, for running off the waste lye. Kiers are commonly made of cast iron, and are capable of containing from 300 to 600 gallons of water, according to the extent of the business done. In order that the capacity of the boilers may be enlarged, they are formed so as to admit of a crib of wood, strongly hooped, or, what is preferable, of cast iron, to

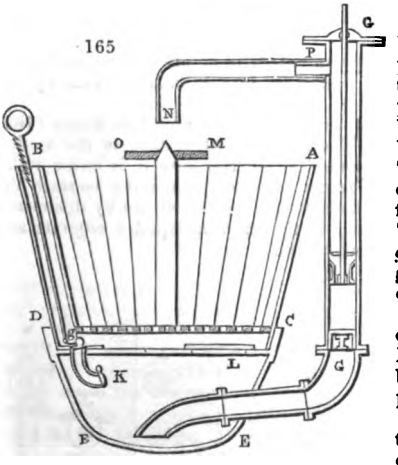
Digitized by Google

be fixed to the upper rim or edge of it. To keep the goods from the bottom, where the heat acts most forcibly, a strong iron ring, covered with netting made of stout rope, c, is allowed to rest six or eight inches above the bottom of the boiler. Four double ropes are attached to the ring, E, for withdrawing the goods when sufficiently boiled, which have each an eye for admitting hooks from the running tackle of a crane. Where more boilers than one are employed, the crane is so placed that, in the range of its sweep, it may withdraw the goods from any of them. For this purpose, the crane turns on pivots at top and bottom; and the goods are raised or lowered at pleasure, with double pulleys and sheaves, by means of a cylinder moved by cast-iron wheels. The lid is secured by the screw bolts D D, and rings B B. F is a safety-valve.

To avoid the excessive heating needful to drive the liquid through the goods, Mr. John Laurie invented the keir at *fig.* 165.

In this *fig.* 165, A B C D is the wooden kieve, or kier, containing the cloth; C E F D represent the cast-iron boiler; G G, the pump; *g* K, the pipe of communication between the kier and the boiler. This pipe has a valve on each of its extremities: that on the upper extremity, when shut, prevents the lye from running into the boiler, and is regulated by the attendant by means of the rod and handle *g* B. The valve at K admits the lye; but, opening inwards, it prevents the steam from escaping through the pipe *g* K. The boiler has a steam-tight iron cover, *g* L; and at C D in the kier is a wooden grating, a small distance above the cover of the boiler.

165



At M O is a broad plate of metal, in order to spread the lye over the cloth. It is hardly necessary to say that the boiler has a furnace, as usual, for similar purposes.

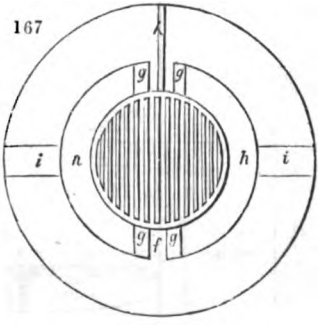
While the lye is at a low temperature, the pump is worked by the mill or steam-engine. When it is sufficiently heated, the elasticity of the steam forces it up through the valves of the pump, in which case it is disjoined from the moving power.

N P is a copper spout, which is removed at the time of taking the cloth out of the kier.

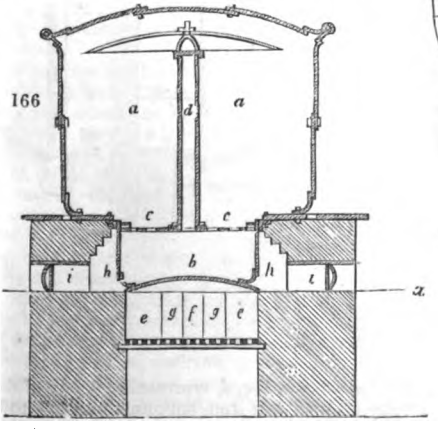
In order still further to avoid labour, the pumping has been entirely done away with.

A simple modification of the bowking apparatus is shown in *figs.* 166, 167, 168; the first being a vertical section, the second a horizontal

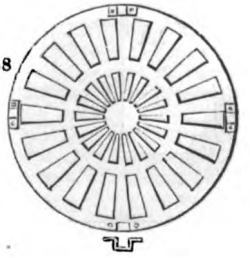
167



166



168



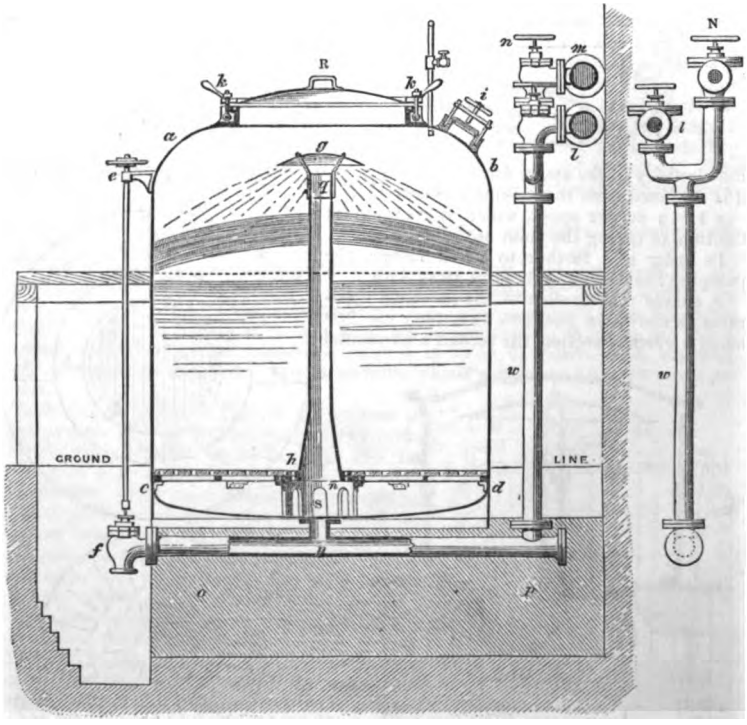
Digitized by Google

section in the line *x* of the first. It consists of two parts: the upper wide part, *a a*, serves for the reception of the goods, and the lower or pot, *b*, for holding the lye; *c c* is an iron grating, shown apart in *fig.* 168. The grating has numerous square apertures in the middle of the disc, to which the rising pipe *d* is screwed fast. The upper cylinder is formed of cast iron, or of sheet iron well riveted at the edges; or sometimes of wood, this being secured at its under edge into a groove in the top edge of the lye-pot. The mouth of the cylinder is constructed usually of sheet iron. *e e* is the fire-grate, whose upper surface is shown in *fig.* 166: it is made of cast iron in three pieces. The flame is parted at *f*, and passes through the two apertures *g g*, into the flues *h h*, so as to play round the pot, as is visible in *fig.* 167, and escapes by two outlets into the chimney. The apertures *i i* serve for occasionally cleaning out the flues *h h*, and are, at other times, shut with an iron plate. In the partition *f*, which separates the two openings *g g*, and the flues *h h*, running round the pot, there is a circular space at the point marked with *k*, *fig.* 167, in which the large pipe for discharging the waste lye is lodged. The upper large cylinder should be encased in wood, with an intermediate space filled with sawdust, to confine the heat. The action of this apparatus is exactly the same as that already explained.

Besides the boiling, bucking, and other apparatus above described, the machinery and utensils used in bleaching are various, according to the business done by the bleacher.

The kier of Messrs. Mather and Platt is very complete. The first figure (169) is the kier when shut or screwed down. The second (170, p. 328) is the section of the kier, which is very like that before given; but in this case it is steam tight, and heated by steam which issues from a steam pipe communicating beneath the false bottom. The dangers attending the kier before mentioned are by this means entirely averted, and all the inventions which give the washing liquid a separate and distinct place for heating are at once done away with.

169

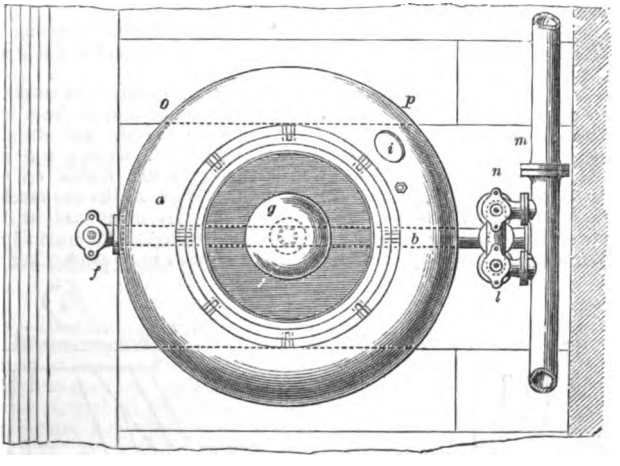


An exact description of these kiers is required. *a*, *b*, *c*, *d*, represent the body of the kier, which is a cylindrical vessel, generally made of cast iron, but sometimes of wood,

Digitized by Google

or wrought iron. *h* represents false bottom; a cast-iron grating, sometimes covered with boulder stones, and sometimes with wood; *g*, cylindrical disc, of wrought iron,

170



placed on the top of "puffer-pipe" *q*, to spread the liquor over the cloth. *q*, "puffer-pipe," standing on false bottom, *h*. *s*, cylindrical casting for supporting false bottom and "puffer-pipe," whose periphery is "slotted," to admit of the liquor passing through. *r*, cover for kier; the flanch on which this cover rests is grooved a little, to admit of "gasking" being inserted, so as to form a "joint." *k*, *k*, swivel bolts, holding down the cover. *i*, a small aperture, covered with a lid capable of being removed easily, to enable the attendant to see that the cloth does not rise too high in the kier to endanger its working; if such happens, he checks the steam until the cloth settles, after which it does not again attempt to rise. *n*, steam valve; *l*, water valve; both communicate with pipe *w*, leading to kier. *p*, pipe communicating with kier for supplying steam and water — also serves as escape-pipe; *f*, escape-valve for letting off kier; *e*, wheel for opening ditto; *m*, steam pipe from boiler. *o*, *p*, foundation for kier.

The process of cleansing is very various. Some use lime for the first process; some use soda alone; some use them mixed. Of course when carbonate of soda and lime are used, caustic soda is at once formed, and the carbonate of lime is left idle. The practices and fancies of bleachers are numerous; and we have only to say that the principle consists in the use of alkaline lyes. Some use lime to the amount of 3 per cent.; others go as high as 10. The lime is slaked first and a portion thrown in; a portion of cloth is laid upon it, and a portion of lime again covers that; but on no account must the goods be allowed to lie in contact with the atmosphere and the lime.

When removed from the kiers the goods must be washed. Now if they are to be washed in dash-wheels, it is needful that they be in separate pieces, and in this state they are sometimes boiled in the kiers; but if they are to be washed in the washing machines, they are lifted out of the kier in the same manner as a piece of string is drawn out of the canister in which the coil is kept.

M. Metz, of Heidelberg, has attempted to perform the work of boiling by merely extracting the air from the cloth. For this purpose the cloth is simply put into a strong upright cylinder, the top screwed down, and the air taken out by an air-pump. We have no knowledge as to the advantages gained by this process, or whether it has been found actually capable of putting cloth in a condition to be bleached for a very fastidious market.

Steeping.—Instead of boiling in the kier at first, the goods are sometimes, though now rarely, steeped from one to two days in water, from 100° to 150° F., for the purpose of loosening the gummy, glutinous, and pasty materials attached to the cloth. Fermentation ensues, and this process is dangerous, as the action of the ferment sometimes extends to the goods, especially if they are piled up in a great heap without being previously washed. The spots of grease on the insoluble soaps become thereby capable of resisting the caustic alkalis, and are rendered in some measure indelible;

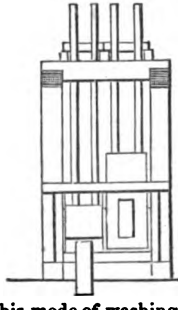
Digitized by Google

an effect due, it is believed, to the acetic and carbonic acids generated during fermentation. Some persons throw spent lyes into the fermenting vats to counteract the acids. The spots of grease are chiefly to be found in hand-loom goods, and the difficulty concerning the fats is not therefore commonly felt where power-loom goods are chiefly used, as in Lancashire.

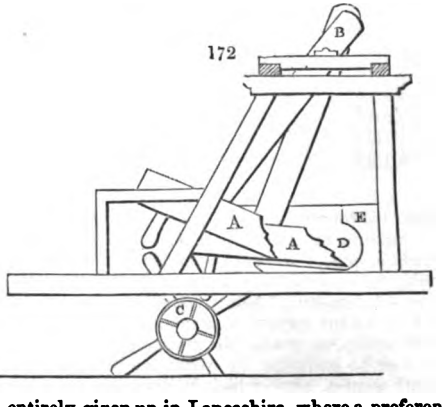
Washing. — If the cloth is to be washed without having the pieces strung together, the following methods may be adopted. The stocks are still used, but not in any large establishments in Lancashire.

Figs. 171, 172, represent a pair of wash-stocks. A A are called the stocks, or feet. They are suspended on iron pivots at B, and receive their motion from wipers on the revolving-shaft C. The cloth is laid in at D, and, by the alternate strokes of the feet, and the curved form of the turnhead E, the cloth is washed and gradually turned. At the same time, an abundant stream of water rushes on the cloth throughout holes in the upper part of the turnhead. Wash-stocks are much used in Scotland and in Ireland. In the latter country, they are often made with double feet, suspended above and below two turnheads, and wrought with cranks instead of wipers. Wash-stocks, properly constructed, make from 24 to 30 strokes per minute.

171



172

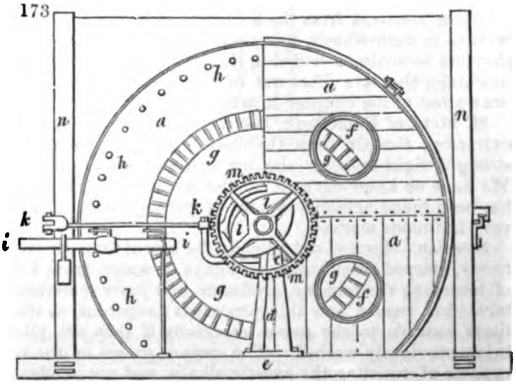


This mode of washing is now entirely given up in Lancashire, where a preference is given to dash-wheels and washing machines with squeezers. The dash are small water-wheels, the inside of which is divided into four compartments, and closed up, leaving only a hole in each compartment for putting in the cloth. There are, besides, small openings for the free admission and egress of the water employed in cleansing. The cloth, by the motion of the wheel, is raised up in one part of the revolution of the wheel; while, by its own weight, it falls in another. This kind of motion is very effectual in washing the cloth, while, at the same time, it does not injure its strength. The plan, however, where economy of water is of any importance, is very objectionable; because the wheel must move at by far too great a velocity to act to advantage as a water-wheel.

The wash or dash-wheel, now driven by steam power in all good bleach and print-works, is represented in *fig* 173, upon the left side in a back view, and upon the right side in a front view (the sketch being halved). *Fig.* 174 is a ground plan.

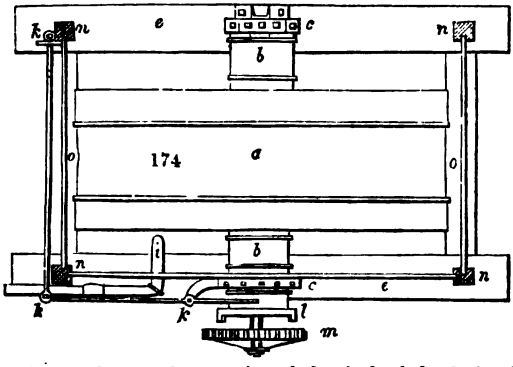
a a is the washing-wheel; *b b* its shaft-ends; *c c* their brass bearings or plummer-blocks, supported upon the iron pillars *d d*. The frame is made of strong beams of wood, *e e*, bound together by crossbars with mortises. *f f*, two of the circular apertures, each leading to a quadrantal compartment within the dash-wheel. In

173



Digitized by Google

the back view (the left-hand half of the figure) the brass grating, *g g*, of a curvilinear form, is seen, through which the jets of water are admitted into the cavity of the wheel; *h h* are the round orifices, through which the foul water runs off, as each quadrant passes the lower part of its revolution; *i*, a water-pipe, with a stop-cock for regulating the washing-jets; *k k*, the lever for throwing the driving-crab *l*, or coupling-box, into or out of gear with the shaft of the wheel. This machine is so constructed, that the water-cock is opened or shut by the same leverage which throws the wheel into or out of gear. *m*, a wheel, fixed upon the round extremity of the shaft of the dash-wheel which works into the toothed pinion connected with the prime mover. When the end of the lever *k*, whose fork embraces the coupling-box upon the square part of the shaft, is pushed forwards or backwards, it shifts the clutch into or out of gear with the toothed wheel *m*. In the latter case, this wheel turns with its pinion without affecting the dash-wheel. *n n*, holdfasts fixed upon the wooden frame, to which the boards *o o* are attached, for preventing the water from being thrown about by the centrifugal force.



The dash-wheel is generally from 6 to 7 feet in diameter, about 30 inches wide, and requires the power of about two horses to drive it.

A dash-wheel has one piece of cloth in each of the four compartments; these are washed in eight minutes, being 30 pieces an hour, or 300 pieces a day; sometimes two pieces are put in, when double the time is given. It generally requires 60 gallons of water per minute to feed it, 36,000 gallons a day, or 120 to a piece. Always after washing, the squeezers are applied, as they remove at once the superfluous water.

The machine made by Mr. Mather (*figs.* 175 and 176) washes 800 pieces per hour, or 8000 pieces per day of ten hours, using 400 gallons per minute, or 120,000 gallons per day, or 20 gallons to a piece. This class of machine is now in its turn superseding the dash-wheel.

This washing machine will be understood by the general plan (*fig.* 176, and corresponding section, *fig.* 175). *a* and *b* represent the squeezing-bowls. *a*, is 18 inches diameter and 8 feet three inches long; it is made of deal timber. (The lapping of strong canvas at *a''* is for the purpose of giving the "out-coming" pieces an extra squeeze, in order to prepare them for the kiers.) *b* is 24 inches diameter and of the same length as *a*, making 100 revolutions per minute; it is generally made of deal, sycamore, however, being better. *c*, *d*, a strong wooden rail, in which pegs are placed in order to guide the cloth in its spiral form from the edge to the centre of the machine. *h*, *h*, the water-trough, through which the piece passes round the roller *n*. *p*, (*fig.* 175), water-pipe. *t*, water-tap. *m*, *m*, pot-eyes, which may be adjusted to any angle, to guide and regulate the tension of the piece on entering the machine. *l*, side frame, for carrying bowls, &c. *g*, engine (with cylinder, 8 inches diameter) and gearing for driving machine. *w*, weight and lever for regulating pressure on the bowl.

This machine washes 800 pieces per hour, and requires 400 gallons of water per minute. It will serve also to represent the *chemick* and *souring* machine, the only difference being that the bowls are 3 feet 6 inches, instead of 8 feet 3 inches, in length.

The *chemick* and *sour* are brought by turns into the trough, or into similar separate troughs, by a leaden pipe from the mixing cisterns, and are run in to 6 or 8 inches deep.

The washing machine of Mr. Bridson (*fig.* 177, p. 332) is worth attention. In its action the course of the cloth in the water is easily seen; it is chiefly horizontal. This motion had been given by Hellewell and Fearn in 1856; but they had a very complicated machine, and they did not attain the flapping motion which is given to the cloth when it becomes suddenly loose, and is driven violently against the board *a a* as often as *b c* and *e d* are in one line. It is not shown by the drawing that the cloth passes eight times round these wheels. There is a constant stream of water from the pipe *f*, which is flattened at the mouth about one and a half inch in one diameter, and about ten inches in the other. This machine can wash 900 pieces in an hour. It requires

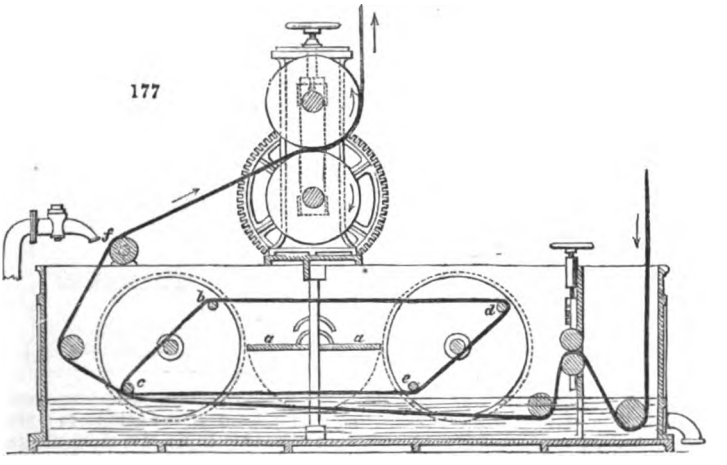
177



about twice as much water as a dash-wheel, but washes seven and a half times more pieces. Its length is nine feet.

Souring. — After boiling in the first kier and washing, the goods are soured in muriatic acid of 1010° specific gravity, or 6½ gallons of the usual acid, which contains 33 per cent. of real acid, mixed with 100 gallons of water. This is equal to 2° Tw. Muriatic acid may be replaced by sulphuric acid of 1024° specific gravity, *i. e.* 3½ gallons liquid acid to 100 of water; — or the amount of the acid may be doubled in either case, and a shorter time allowed for the souring. The souring is performed in wooden or stone cisterns, where the cloth is laid regularly as it falls over one of the rollers of the calender; — or it is passed through the acid solution by the movement of the calender in the same manner as described in the process of washing. If this method is used, it is allowed to lie on the stillages from two to three hours to allow the acid to act. The acid decomposes any lime soap formed, and washes out the lime. Hydrochloric or muriatic acid has been preferred in the process described, as the chloride of calcium is so much more soluble than the sulphate. After souring, of course the goods must be thoroughly washed as before.

The sixth operation with soda removes the remaining fatty materials. If lime be used, it may be allowed to settle; and it is better to allow it to do so, and thus to use pure caustic soda, which will with the resin remove the impurities in a more soluble form. If, instead of adding 170 lbs. of soda crystals to 600 gallons of water, 4·6 lbs. of liquid caustic soda of specific gravity 1320° were added, the effect would be the same.

The solution of resin and carbonate of soda is a half formed soap, which is considered to act beneficially in removing the soluble matter. It would not appear, from theory, to be capable of doing so well as the soda which has its carbonic acid removed; but tender goods will not allow the action of caustic soda, and the carbonate is therefore safer.

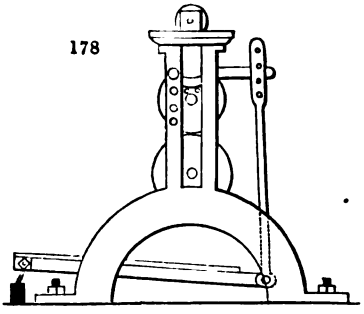
Powder-bleaching.—Chloride of lime is added in stone vessels where the goods are allowed to lie. It is universally called *chemick* in the manufactories. The strength used at Brickacre is half a degree Twaddle, or 1002·5. This is sometimes very much increased, so as to be even 5° in some establishments, according to the goods bleached; but it is not safe to allow the cloth to lie long in such strong solutions. In such cases it is needful to pass them rapidly through with the calender, so as to soak them thoroughly, and then to pass them on to the acid, and forward to be washed. It may be remarked that the use of the calender for these operations renders it possible to use strong solutions, even for tender goods, as there is no time given for injurious action on the fibre.

Great care is to be taken to make the solution of the chloride of lime perfectly clear. The powder does not readily wet with water, and it must therefore be pressed or agitated. This may be done by putting it in a revolving barrel with water, until complete saturation of the powder with moisture; the amount required is then thrown into the cistern, and the insoluble matter allowed to sink. This insoluble matter must not be allowed to come into contact with the cloth, as it will be equal of course to a concentrated solution of the liquor, and will produce rottenness, or *burn the cloth* so as to leave holes. When removing from the trough, the cloth is drawn through squeezing rollers, which press out any excess of chloride of lime.

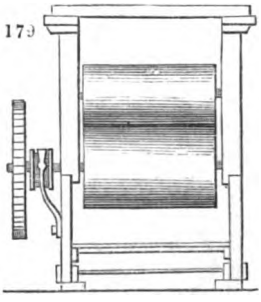
Digitized by Google

Squeezing.—The squeezing rollers or squeezers, for discharging the greater part of the water or any liquid from the yarns and goods in the process of bleaching, are represented in *figs.* 178, 179, the former being a side view, to show how the roller gudgeons lie

178



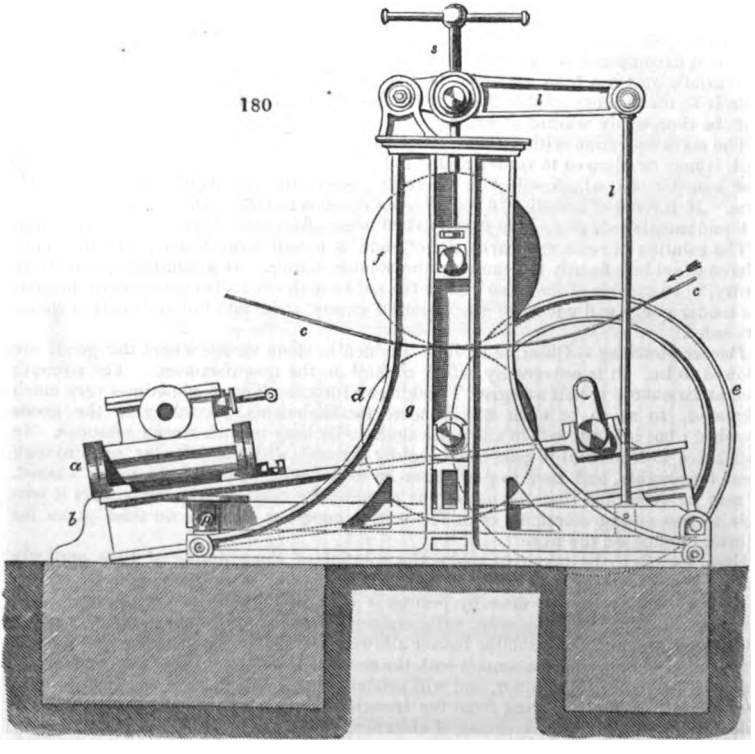
179



in the slots of the frame, and how the shaft of the upper roller is pressed downward by a weighted lever, through a vertical junction road, jointed at the bottom to a nearly horizontal bar, on whose end the proper weight is hung. In *fig.* 179, these rollers, of birch-wood, are shown in face; the under one receiving motion through the toothed wheel on its shaft from any suitable power of water or steam. Upon the shaft of the latter, between the toothed wheel and the roller, the lever and pulley for putting the machine into and out of gear is visible. The under roller makes about 25 revolutions in the minute, by which time three pieces of goods, stitched endwise, measuring 28 yards each, may be run through the machine, from a water trough on one side to a wooden grating upon the other.

A squeezing machine, with a small engine attached, is shown in *fig.* 180, for the drawing of which we are again indebted to the makers, Messrs. Mather and Platt.

180



Digitized by Google

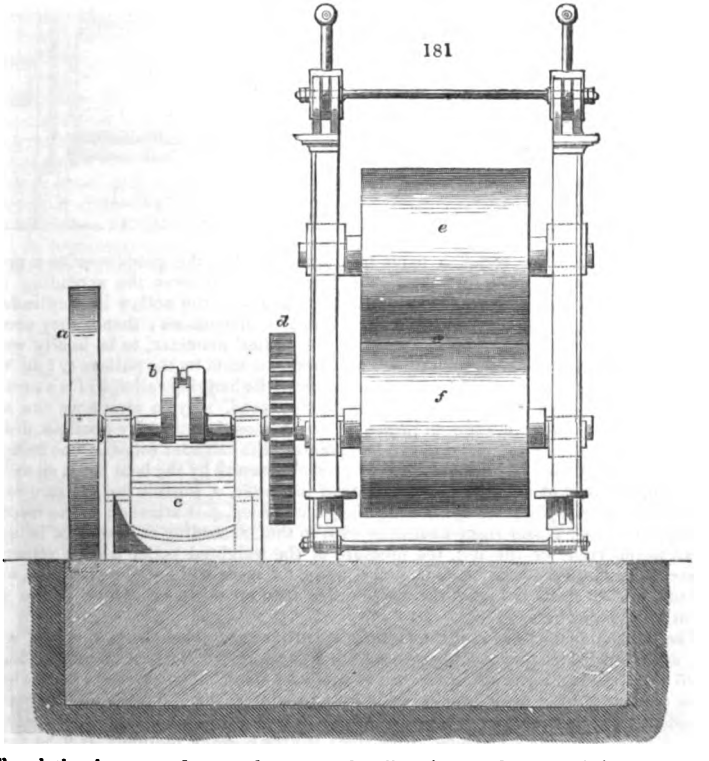
d, *f*, represent the squeezing-bowls. They are as large in diameter as possible, and are generally made of sycamore; but the bottom one is better made of highly compressed cotton. *a*, *b* are the engine and frame for driving; *g*, frame for carrying bowls; *l*, *l*, compound levers for regulating the press use; *s* is a screw for the same purpose, and *c* is the cloth passing through the bowls.

The white-squeezers, or those used before drying, should have a box, supplied with hot water, fixed so that the piece may pass through it before going to the nip of the bowl.

When the goods are run through, they are carried off upon a grated wheelbarrow in a nearly dry state, and transferred to the spreading machine, called at Manchester a *candroy*. In many bleach works, however, the creased pieces are pulled straight by the hands of women, and are then strongly beat against a wooden stock to smooth out the edges. This being done, a number of pieces are stitched endwise together, preparatory to being mangled.

This squeezing machine is small, but, as will be seen, the rollers are introduced so as to act as long and as rapidly as cloth of whatever length is drawn through them.

The following figure (181) represents a pair of squeezers, for squeezing the cloth after several of the processes named, and are shown as being driven by a small high pressure engine. *a* is the fly wheel of engine; *b*, crank of ditto; *c*, frame of engine; *d*, spur wheels connecting the engine and squeezers; *e* and *f*, sycamore squeezing bowls.



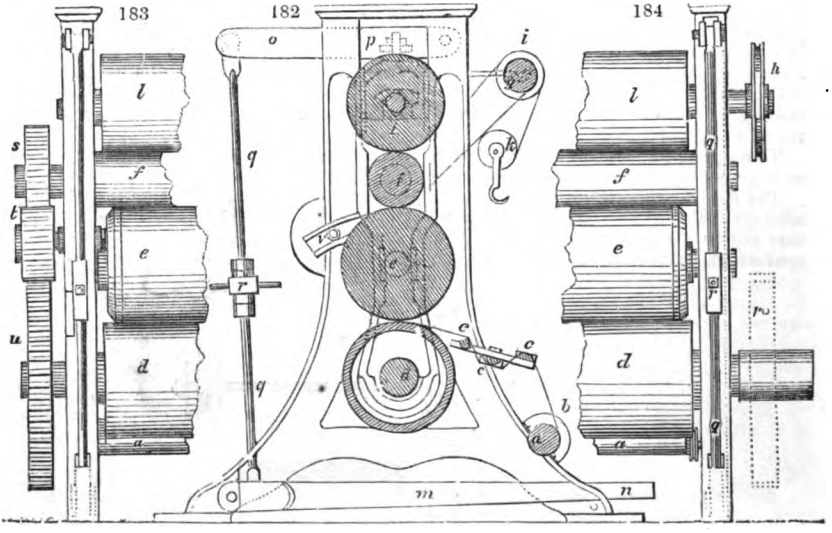
The cloth when passed over the steamed rollers is now dry; but it is not smooth and ready for the market. If the cloth is wanted for printing, no further operation is needed; but if to be sold as white calico, it is finished by being starched and calendered.

The starch at large works is prepared by the bleachers themselves. At Messrs. Bridson's it is made with the very greatest care from flour. Of course it would be more expensive for them to buy it, as the manufacturer would dry it, and they would require to dissolve it. They are able also, in this manner, to obtain the purest starch. This is mixed with blue, according to the finish of the goods. A roller, which dips into the starch, lays it regularly and evenly on the cloth in the same manner as

Digitized by Google

mordants are communicated in calico printing, whilst other rollers expel the excess of the starch. The cloth is then dried over warm cylinders, or by passing into a heated apartment. It receives the final finish generally by the calender; but muslins receive a peculiar treatment.

Calender.—Fig. 182 is a cross section of this machine, and *figs.* 183, 184 are front views broken off. The goods are first rolled upon the wooden cylinder; *a*, near the



ground; by the tension roller, *b*, upon the same cylinder, the goods receive a proper degree of stretching in the winding off. They then pass over the spreading bars, *c c c*, by which they are still more distended; next round the hollow iron cylinder, *d*, 16 inches diameter, and the paper cylinder, *e*, of like dimensions; thence they proceed under the second massive iron cylinder, *f*, of 8 inches' diameter, to be finally wound about the projecting wooden roller, *g*. This is set in motion by the pulleys *h*, (*fig.* 184), and *i* (*fig.* 182), and receives its proper tension from the hanging roller, *k*; *l* is a pressing cylinder of 14 inches' diameter, made of plane-tree wood. By its means we can at all times secure an equal degree of pressure, which would be hardly possible did the weighted lever press immediately upon two points of the calender rollers. The compression exercised by the cylinders may be increased at pleasure by the bent lever, *m*, weights being applied to it at *n*. The upper branch of the lever, *o*, is made fast, by screws and bolts at *p*, to the upper press cylinder. The junction leg, *q*, is attached to the intermediate piece, *r*, by left and right-handed screws, so that, according as that piece is turned round to the right or the left, the pressure of the weighted roller will be either increased or diminished. By turning it still more, the piece will get detached, the whole pressure will be removed, and the press roller may be taken off, which is the main object of this mechanism.

The unequable movement of the cylinders is produced by the wheels *s*, *t*, *u*, of which the undermost has 69, the uppermost 20, and the carrier-wheel, *t*, either 33, 32, or 20 teeth, according to the difference of speed required. The carrier-wheel is bolted on at *v*, and adjusted in its proper place by means of a slot. To the undermost iron cylinder, the first motion is communicated by any power, for which purpose either a rigger (driving pulley) is applied to its shaft at *u*, or a crank motion. If it be desired to operate with a heated calender, the undermost hollow cylinder may be filled with hot steam, admitted through a stuffing box at one end, and discharged through a stuffing box at the other, or by a red-hot iron roller.

Before passing through the press, they are slightly damped; this is done by a roller of brushes, which dips into the water, and throws it regularly on the cloth. They are then subjected to the powerful pressure of the calender rollers. The calendered pieces, by the powerful pressure of the rollers, are smooth and somewhat shining. There can be no doubt that cloth in this state looks to the best advantage. The pieces must, however, be put into a compact form. This is done by folding them into parcels, which are pressed by hydraulic power into firm and solid masses. Each parcel has

Digitized by Google

the mark of the manufacturer, or any device that he may choose to have, stamped upon it or bound round it.

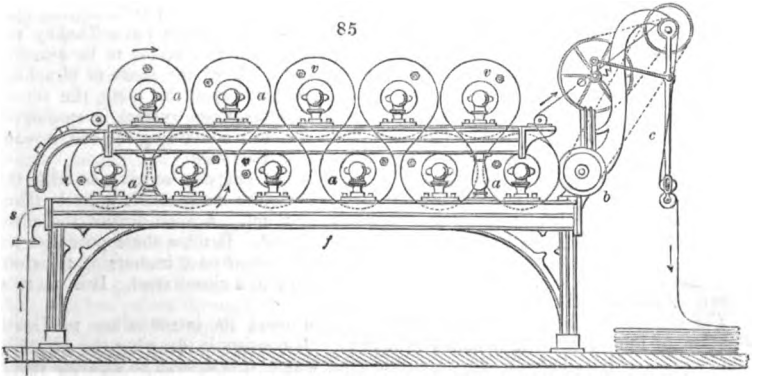
Finishing.—Pure starch is not always used for the purpose of finishing. Fine clay, gypsum, or Spanish white, is mixed with the cloth; and if weight is desired to be given, sulphate of baryta is employed. Mr. John Leigh, of Manchester, has lately patented for this purpose the use of silicate of soda, which, for such goods as are not injured by alkalis, seems to answer the purpose at a very cheap rate. There can, however, be no doubt that too much attention is given to this finish for home goods, or for all purposes which require the goods to be washed: they assume a solidity of appearance which they do not possess when the finishing material is removed from the pores, and the cloth appears without disguise. In some instances, however, this finish is a peculiarity of the goods, and is almost as important as the cloth itself. For example: in the case of muslins, when they are dried at perfect rest, they have a rigid inelastic feeling, somewhat allied to that of thin laths of wood, and feel very rough to the touch. They are therefore dried by stretching the cloth, and moving the lines of selvage backward and forward, so as to cause the threads of weft to rub against each other and so as to prevent them becoming united as one piece. Goods dried in this manner have a peculiar spring, and such thick muslins are for a time possessed of great elasticity. Several pieces folded up in a parcel spring up from pressure like caoutchouc.

Mr. Ridgeway Bridson invented an apparatus for giving this peculiar finish to muslins. Formerly it was done entirely by the hand, and in Scotland only. Since the invention of this machine, this trade has become a very important one in the Manchester district.

Sometimes goods are finished by the beetle, which acts by repeated hammering. This peculiar action has been transferred to a roller by T. R. Bridson, and called the "Rotatory Beetle." It consists of a cylinder having alternately raised and depressed surfaces, and two other cylinders which press upon it, and alternately press the cloth and give a freedom as it passes between the rollers. This is similar to the rise and fall of the hammers or mallets in the beetling process.

Sometimes a stiff finish is wanted; then muslins are dried in the usual way.

Drying.—Figs. 185 and 186 represent a drying machine, with eleven cylinders, each 22 inches in diameter, capable of drying 1000 pieces of bleached calico in a day. *a*, represents cylinders heated with steam; *v*, vacuum-valves in ditto; *f*, frame for carrying cylinders; *c*, folding apparatus; *s* steam-pipe; *y*, gearing.



When goods are dried having a raised pattern, such as brocades, or any other, such as striped white shirting, only one side of the cloth is to be exposed; the pattern rises up from the heated surface on which the cloth is dried. For this reason, cylinders such as those just described cannot be used. Large wheels of cast iron are employed, consisting of two concentric cylinders, between which is a closed space heated by steam. The cloth is by this means heated on one side only, not passing from cylinder to cylinder, in which case the side next to the heating surface would be changed every time. The larger the cylinder or wheel, the more rapid is the drying, as there is more surface of cloth exposed to it at a time; it can, for the same reason, be turned more rapidly round. Well-finished goods will not rise when heated, except on the pattern. Messrs. Bridson have a large business in jacconets for artificial flowers on account of this peculiar finish. They are formed of a plain cotton cloth, but stand the pressure of hot irons without curling.

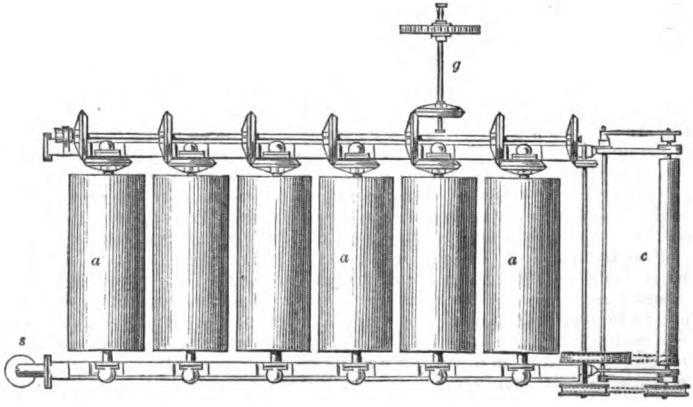
186



No essential difference is made in bleaching muslins, except that sometimes weaker solutions are employed for very tender goods. Mr. Barlow makes no difference as a rule in the strength given in describing his process; with very strong goods, he sometimes uses the liquids stronger.

It is desired occasionally to bleach goods which have coloured threads woven into them, or colours printed on them. In these cases great caution must be used. It is needful to use weak solutions, but more especially not to allow any one process to he continued very long, but rather to repeat it often than to lengthen it. This may be stated as a general rule in the bleaching of goods. It would indeed be possible to do the whole bleaching in one operation, but the cloth would be rotten. This arises from the fact that, at a certain strength, bleaching liquor or soda is able to destroy the fibre; but another and less strength does not act on the fibre, but only on such substances as colouring matters. This care is needed when printed goods which have a white ground are treated. The white ground takes up colour enough to destroy its brilliancy, and soaping does not always remove it. The bleaching then is effected by using bleaching liquor at ½ Twad. Some persons put a Turkey red thread into the ends of the pieces. The original use of this seems to be scarcely known among the manufacturers. It was used as a test of the mode of bleaching employed. If strong solutions be used, which are apt to spoil the cloth, the colour of the dyed threads will be discharged. When the separate system is employed, this is evaded easily; it is the practice to keep the ends containing the red threads out of the liquid, allowing them to rest on the side of the vessel.

Sometimes chlorate of potash is used for the same purpose, souring as with the bleaching powder. The colours may, in this manner, be made much more brilliant than before, although a little excess will discharge them. A good deal of the effect may be owing to the better white given to the ground. Besides these processes for bleaching, another was at one time introduced, which consisted of immersing the cloth in a solution of caustic alkali, and afterwards steaming in a close vessel. It is not now in use. Alkali of 1020° specific gravity was used.

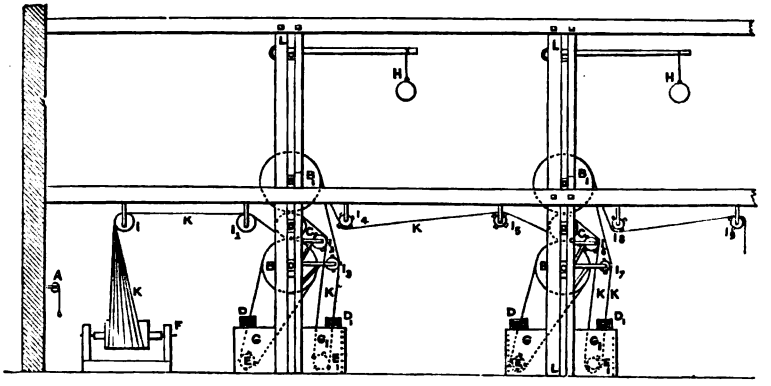
The new or continuous process. This method owes its introduction to David Bentley, of Pendleton, who patented it in 1828. It consists in drawing the goods in one continuous line through every solution with which it is desired to saturate them. This is done by connecting the ends of all the pieces. The motion of rollers draws the chain of cloth thus formed in any desired direction, and through any number of solutions any given number of times. We shall allow him to use his own words

Fig. 187 (p. 338) is an end view of two such calenders, each having two larger rollers B and B 1, a smaller driving roller C, two racks D and D 1, placed upon two cisterns G and G 1, inside of which cisterns are two rollers E and E I, which rollers have four square ribs upon each, to shake the goods as they pass through the cisterns. At F is a frame upon which the batches of goods are placed upon rollers shown in *fig.* 188 (p. 338), where they are marked K, K, K, K. The calender cheeks are made fast at the feet, at the middle, and to the top of the building, having levers and weights H to give pressure to the calender bowls.

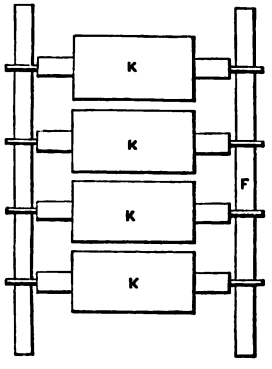
Near the end walls of the building are two rollers, one of which is shown at A; upon each of these is a soft cord used as a guide for conducting the goods through the machinery and cisterns. The operation is commenced by passing one end

Digitized by Google

187



188



of the cord through the rollers B and C, down to cistern G, under roller E, through the furthermost division of rack D, and again through calender rollers at B and C, repeating the same, but observing to keep the cord tight, and to approach one division nearer in rack D each revolution until each division is occupied, when the end must pass over C, under and round B 1, down to and over the guide roller I 3, through the nearest division of rack D 1 into cistern G 1, under roller E 1, over guide roller I 2, and again over roller C, under and round B 1. This course must be repeated, observing as before to keep the cord tight, and to receive one division of rack D 1 every revolution, until each division of rack D 1 is occupied, when the end must pass over from B 1 under I 4. The cord now forms a sort of spiral worm round and through the machinery and cisterns, beginning at B, C, and ending at the top of B 1 to I 4, the number of revolutions being governed by the number of divisions in the racks D and D 1, so that if there were fifteen divisions in each rack there would be fifteen revolutions under C, round B through G, under E through D, and fifteen revolutions over C round B 1, over I 3 through D 1 and G 1, under E 1 over I 2, and again over C, passing from the top of B 1 to I 4; and by this means, if one end of the back of goods marked K, and placed upon the frame F (*fig.* 188), is fastened to the end of the guide cord, the goods will, when the calender is put in motion, be conducted and washed thirty times through the water in the cisterns, and squeezed thirty times through the calenders. As the operation proceeds and the guide cord passes through the calender, it is wound by hand upon roller A to prevent it from becoming entangled, and to keep it in readiness for the next operation. As soon as the first end of the goods has passed through *fig.* 188, and arrives at the guide roller I 4, it is detached from the end of the guide cord and attached to the guide cord at the other end, or with the opposite set of calenders. After this, by putting these in motion, the goods are washed and squeezed through its cisterns, which cisterns are supplied with hot and strong lime lye, and the goods passing over guide roller I 9, they are conveyed over other guide rollers to be placed for the purpose, and taken down by some person or some proper machinery into one of the boiling vessels, where, steam or fire heat being added, they are suffered to remain while the lime-boiling takes effect.

We need not follow the inventor into all the particulars. When the goods were sufficiently acted on by one solution, another solution was used, so that this mode of calendering not only was a method of moving the goods from place to place by means of rollers, but it was a method also of saturating goods thoroughly with a solution, and of washing them.

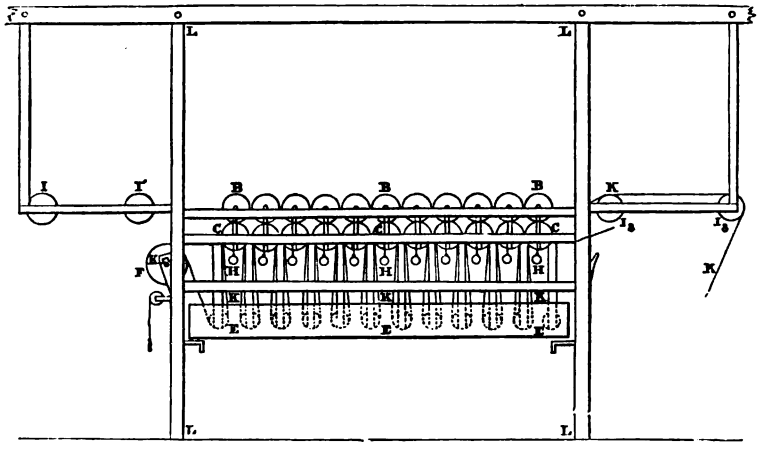
It was by a similar methed that Mr. Bentley bleached skeins of yarn, of linen, or of cotton. The skeins are looped together by tying any soft material round the middle of the first skein, which will leave the loops from one end of the next skein to pass half way through, and which will always leave other two loops, and by re-

Digitized by Google

peating which any quantity of skeins may be looped together, tying the last loop with another soft material.

The mode of saturating the goods with solutions is effected by the arrangement shown in *fig.* 189. Rapid motion and frequent pressure are introduced instead of a still soaking process.

189



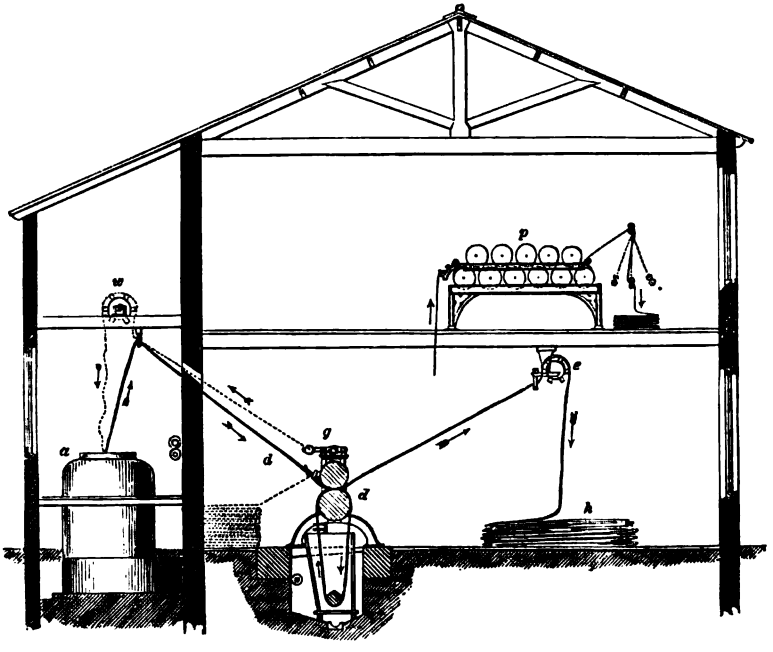
A is a roller for the guide cords; B, B, B, are eleven washing rollers; C, C, C are speed rollers; E, E, E are twelve rollers immersed in twelve divisions of the cistern G. The eleven staple-formed irons which pass through the frame rails on each side of the centres of the eleven rollers B, B, B, and the eleven rollers C, C, C, serve to stay these rollers in their places, at the same time allowing the eleven washing rollers B, B, B, to rise and fall according to the pressure by which they are held down by the eleven weights attached to these irons at H, and upon the bottom rail may be placed such staves, brushes, or rollers, as may be found necessary for holding and brushing the goods in the best manner to keep them straight during the different washings in water and bleaching liquors. The goods are prepared by steeping, as before described, and placed in batches at F, and passing under the immersing rollers E and the twelve divisions of cistern G, between the eleven speed rollers C and the eleven washing rollers B, as seen at K, are taken down straight and open into one of the vessels, and are then boiled by steam, which is succeeded by repeated washings alternately in water and bleaching liquors, until they are sufficiently bleached, as before described.

The elevation and ground-plan of a bleach-house and machinery capable of bleaching 800 pieces of 4 lbs. cloth per day (for best madder work), with the labour of one man and three boys, working from 6 until 4 o'clock, exclusive of singeing and drying, are represented in *figs.* 190 and 191 (p. 340). The letter *d* represents two lengths of cloth of 400 pieces each (end of pieces being stitched together by patent sewing machine made by Mather and Platt), making together 800 pieces, passing through washing machine, *g*, and from thence delivered over winch, *w*, into kier, *c*, — this operation occupies one hour, — where they are boiled for twelve hours in lime. They are then withdrawn by the same washing machine, *g*, washed, and passed into second kier, *b* (operation occupying one hour), where they are boiled for twelve hours in ashes and resin; again withdrawn by the same machine, *g*, washed, squeezed (see plan at U), and passed over winch, *e*, and piled at *h* (this operation occupies one hour). They are then taken from pile, *h*, and threaded through sour-machine, *e*, soured, passed over winch, *e''*, and piled at *k* (operation, one hour), where it remains in the pile for three hours. It is then squeezed at U, and washed through machine, *g* (an hour's operation), delivered into third kier, *a*, boiled for six hours, washed at *g*, squeezed at U (an hour's operation), and passed through *chemick-machine* (an hour's operation), and piled for one hour; after which it is soured again (an hour's operation), squeezed, and washed at *g* (an hour's operation), squeezed again at *f* (an hour's operation), and dried by machine at *p* (*fig.* 190).

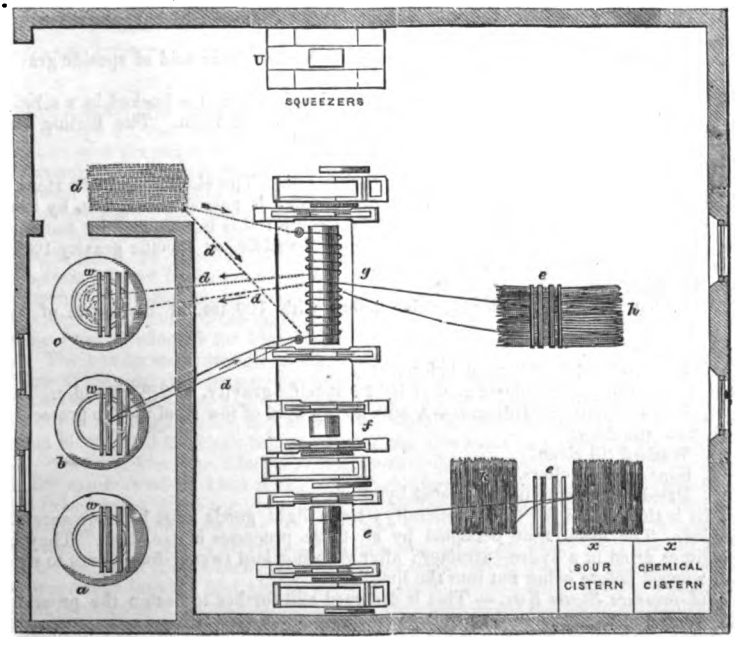
There are several advantages in using the squeezing process so often in the above arrangement:—Firstly, The bowls of the washing maching are not so much damaged

Digitized by Google

190



191



Digitized by Google

by the heavy pressure which is required to be applied, if no squeezers are used, in order to prepare the pieces for the sour and chemick machines: Secondly, A drier state of the cloth than can possibly be produced by the washing machine *alone*, thus fitting it to become better saturated with the chemick or sour: Thirdly, The piece passing from the souring to the washing machine, in this arrangement, carries with it *less* of the acid, and thus ensures a better washing with less water.

It may be observed, that the velocity of the above-mentioned machines is much higher than usual, experience having shown that the various operations are thus better performed than when running slower. The reason of this appears to be, firstly, that the piece, running at such velocity, carries with it, by reason of capillary attraction, a greater quantity of liquid to the nip of the bowls; secondly, the great velocity of the bowls, together with the greater quantity of water carried up, produces a more powerful current at the *nip* and down the ascending piece, thus penetrating to every fibre of it.

It may also be remarked, that the above-mentioned machines are not adapted to the bleaching of linen; for the latter cloth, not having the same elasticity as cotton, if it should become tight, would either be pulled *narrow* or torn.

In illustration of the continuous process as at present used, the plan of proceeding at Messrs. McNaughten, Barton, and Thom's, at Chorley, may be described.

1. In order that there may be no interruption in the process, the pieces are united in one continuous piece — each piece being about 30 yards, the whole varying with the weight of cloth — about 300 yards long. Each piece is marked with the name of the printer. This is sometimes done in marking-ink of silver, and sometimes in coal-tar, at the extremity of the piece. The pieces are rapidly tacked together by girls, who use in some establishments a very simple sewing machine. (See SEWING MACHINE.) The whole amount to be bleached at a time is united in one piece, and is drawn from place to place like a rope. To give them this rope form, the goods are drawn through an aperture whose surface is exceedingly smooth, being generally of glass or earthenware. Of these many are used in transferring the cloth from place to place. They serve instead of pulleys. The cloth when laid in a vessel is not thrown in at random, but laid down in a carefully made coil. The rope form enables the water to penetrate it more easily.

2. The pieces are singed.

3. They are boiled in the first kier. In this, 3500 lbs. of cloth have added to them 250 lbs. of caustic lime, 1 lb. of lime to 14 of cloth. The kier is cylindrical, 7 feet deep and 8 feet in diameter; as much water is added as will cover the cloth, about 500 gallons. This boiling lasts thirteen hours.

4. They are washed in the washing machine. Robinson and Young's machine is used.

5. They are soured in a similar machine with hydrochloric acid of specific gravity 1010·, or 2° of Twaddle.

6. The same amount of cloth being supposed to be used, it is bucked in a solution of soda-ash and resin, 170 lbs. of soda-ash to 30 lbs. of resin. The boiling lasts sixteen hours, the same amount of water being used.

7. Washed as before.

8. Passed through chloride of lime, or chemicked. The cloth is laid in a stone or wooden cistern, and a solution of bleaching powder is passed through it, by being poured over it and allowed to run into a vessel below; this is managed by continued pumping. This solution is about half a degree Twaddle, or specific gravity 1002·5. The cloth lies in it from one to two hours.

9. Washed.

10. Boiled again in a kier for five hours with 100 lbs. of carbonate of soda crystals.

11. Washed.

12. Put in chloride of lime as before.

13. Soured, in hydrochloric acid of 1012·5 specific gravity, or 2½° Twaddle.

14. Lies six hours on stillages.—A stillage is a kind of low stool used to protect the cloth from the floor.

15. Washed till clean.

16. Squeezed in rollers.

17. Dried over tin cylinders heated by steam.

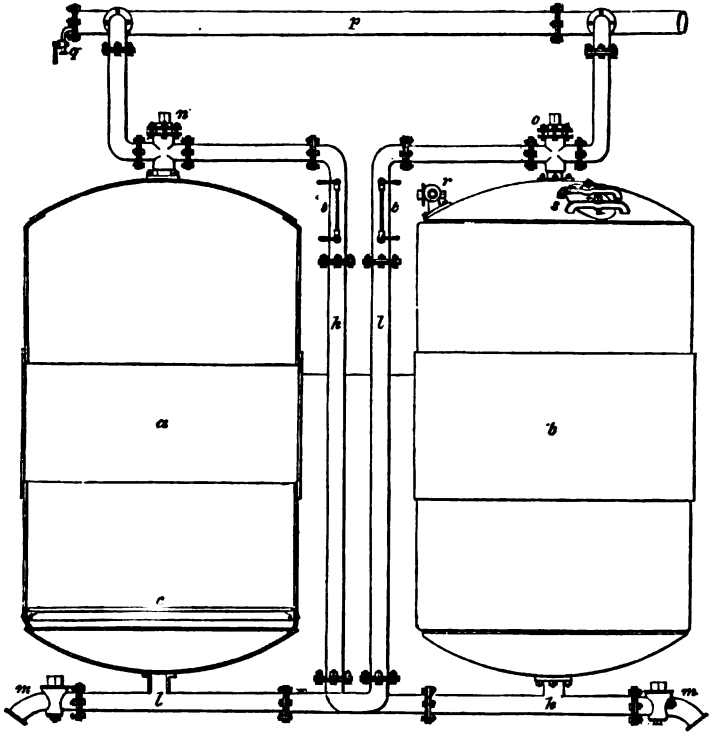
This is the process for calico generally; some light goods must be more carefully handled. The usual time occupied by all these processes is five days. They are sometimes dried in a hydro-extractor; after singeing, laid twenty-four hours to steep, then washed before being put into the lime kier.

High-pressure Steam Kier. — This is designed still further to hasten the process of bleaching, and at the same time to improve it.

Digitized by Google

Fig. 192 is an elevation showing the arrangement of these kiers (which are recommended to be made of strong boiler-plate iron). One of these is shown in section. *a* and *b* are the kiers; *c* is a perforated platform, on which the goods to be bowked are

192



laid; *k k* is the pipe connecting the bottom of the kier *b* with the top of the adjoining kier, *a*; and *l*, *l*, the corresponding pipe connecting the opposite ends of the kiers *a* and *b*; *m m* are draw-off cocks, connected with the pipes *k* and *l*, by which the kiers can be emptied of spent liquor, water, &c.; *n* and *o* are ordinary two-way taps, by which the steam is admitted into the respective kiers from the main pipe, *p*, and the reversing of which shuts off the steam communication, and admits the bowking liquor as it becomes expelled from the adjoining kier; *q* is a blowing-off valve or tap; *r*, the pipe through which the bowking liquor enters into the kier; *s*, manhole (closed by two cross bars, secured by bolts and nuts) through which the goods are introduced and removed; *t t* are gauges, by which it is ascertained when the liquor has passed from one kier and has entered the other.

The process adopted for bleaching is as follows;

1. The box or water trough of the washing machine is then half filled with milk of lime of considerable consistence, and the goods are run through it, being carried forward by the winches and deposited in the kiers. The whole of the cloth in a kier is in one length, and a boy enters the vessel to lay it in regular folds until the kier is filled. All the cloth before entering the kier must pass through the lime.

2. When the kiers are filled, a grid of movable bars is laid on the top of the cloth, and the manhole of the kiers is closed. High-pressure steam is then admitted at the top; this presses down the goods and removes the lime water, which is drawn off at the bottom. At the same time the air is also removed from the goods and replaced by steam. When this is driven off, and nothing but steam issues from the tap at the bottom, 40 lbs. of lime, which have been previously mixed with 600 gallons of water, are introduced into the first kier in a boiling state. High-pressure steam is again admitted, which forces the lime liquor through the goods to the bottom of the vessel, then

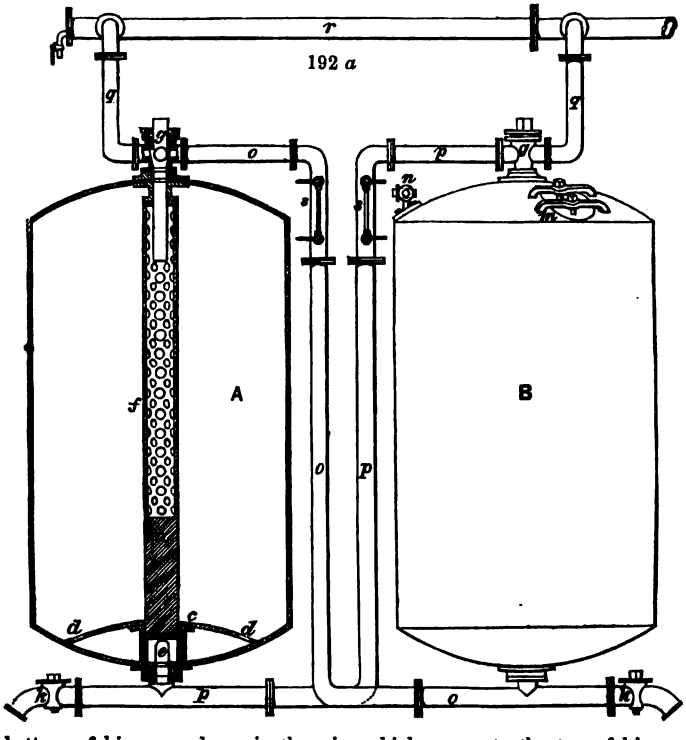
Digitized by Google

up the tube *l*, and on to the goods in the second kier. The tap is then closed which admits steam into the first kier, and the steam is now sent into the second. The same process occurs, only in this case the liquid is sent again on to the top of the goods in the first kier. This process is continued about eight hours.

High Pressure and Distributing Kiers.—Mr. Barlow has effected an important improvement in his original high-pressure kiers by the addition of distributors.

Fig. 192*a* is an elevation showing a pair of kiers, fitted with distributors, &c. A and B are the kiers (which it is preferable to make of strong boiler-plate iron), the kier A being shown in section, and exhibiting the distributors, &c.

At the bottom of the kier is a plate of an umbrella shape, *c*. This plate spreads over about three-fourths of the bottom of the kier; it is perforated with holes all around its outer ridge, at *d d*, which rests upon the bottom of the kier; all the rest of the plate being solid. This plate is fastened in the centre to an iron block, *e*, which stands upon the bottom of the kier in the centre, over the outlet hole. The block *e* is pigeonholed at the bottom, so as to allow the liquor to pass from the kier. A socket is left in the upper part of the block *e*, to admit the insertion of the distributor *f*. This distributor is made of dimensions corresponding to the size of the kier; it is solid for some distance from the bottom, and above that is hollow and perforated as full as possible with holes until within a few inches of the top of the kier, where it is connected with the tap *g* (an ordinary two-way tap, which admits either steam or liquor, or shuts off both) by an inlet pipe, which dips for some distance inside the distributor. *o o* is the pipe connecting the top of the kier A with



the bottom of kier B, and *p p* is the pipe which connects the top of kier B with the bottom of kier A; *q q* are steam pipes from the main pipe *r*; *m* is the manway, through which the goods are introduced and removed; *n* the pipe and tap, through which the working liquor enters the kier; *s s* are gauges, by which it is seen when the liquor has passed from one kier and has entered the other; *k k* are draw-off taps connected with the pipes *o* and *p*, by which the kiers can be emptied of spent liquor, water, &c.

The distributors give a circulation of liquor and steam from the centre of the kiers to the goods all around, while by the action of the umbrella plate the liquor is prevented escaping until all the goods are thoroughly saturated with it every time the

Digitized by Google

liquor is forced through them; they also greatly accelerate the circulation of the liquor through the goods, and there is no necessity for anything being laid upon the goods to keep them in their place. The kiers may be crammed full of goods, and either high or low pressure steam may be used in working them.

The process adopted for bleaching is as follows; it is the shortest and simplest in use.

1. After singeing, the water box or trough of the washing machine is half filled with milk and lime of considerable consistence, and the goods are run through it being carried forward by the winders and deposited in the kiers, a boy being in each kier, who lays the goods in regular folds until the kier is filled.

2. When the kiers are filled, the manholes are closed. High pressure steam is then admitted at the top, this presses down the goods and removes the lime water which is drawn off at the bottom, at the same time the air is also removed from the goods and replaced by steam. When this is driven off and nothing but steam issues from the tap at the bottom, 40 lbs. lime, which have been previously mixed with 600 gallons of boiling water, are introduced into the first kier in a boiling state. High pressure steam is again admitted, which forces the lime liquor through the goods to the bottom of the vessel, then up the pipe *o*, and on to the goods in the second kier. The tap is then closed which admits steam into the first kier, and the steam is now sent into the second. The same process occurs, only in this case the liquid is sent again on to the top of the goods in the first kier. This process is continued about five hours.

In this method each 7000 lbs. of cloth take into the kiers 2 cwts. of lime, which is equally distributed. The clear lime water which is blown out of the steam at the commencement contains only 3 to 4 lbs. of lime in solution. At the close of the operation the liquor has a specific gravity of 3½ to 4° Twaddle (1017·5 to 1020), instead of half that amount, or 1½ to 2° Twad. (1007·5 to 1010), as is usual.

3. When the liming is completed the steam pressure in the kiers is removed, the manway opened, and the cloth in the kier attached to the washing machine, which draws the goods out of the kiers and washes them.

4. The pieces are then passed by the winches through the souring machine, or soured by having muriatic acid of 2° Twaddle pumped upon them (1010). They must remain with the acid two to three hours, either steeped in it, or after having passed through it.

5. Again attach the cloth to the washing machine, and wash it well, passing it on by winches, as before, into the kier.

6. Introduce steam and drive off the air and the cold water; these are let out by the tap at the bottom: add then 224 lbs. of soda-ash and 112 lbs of resin, boiled in 600 gallons of water, for 7000 lbs. of cloth. Work the kiers by driving the liquid from one to the other as before; about five hours is a sufficient time. These proportions of soda may be varied. If the cloth is very strong a little more may be used (or if the cloth has been printed upon in the grey state, from having been used to cover the blanket of the calico-printing machine).

7. After this the cloth is passed through the washing machine, and then submitted to chloride of lime. This may be done either by the machine or by pumping. In either case it is an advantage to warm the bleaching liquid up to 80° or 90° F. The strength of the solution when the machine is used may be about ½° Twaddle, or 1002·5 specific gravity; but if the pump is used it must be much weaker. When the bleaching is for finishing white, milk of lime is added to the chloride, in order to retard the operation; the goods are also washed from the bleaching liquor before souring them. This causes a smaller escape of chlorine, and is a more careful method; it tends to preserve the headings, or the coloured threads, which are often put into the ends of pieces of cloth in order to see if the bleaching has been performed roughly or not. The original use of this has almost been forgotten, but these headings are still carefully preserved. This method preserves also the cloth, which is also less apt to be attacked by the chlorine.

If the cloth has been well managed, it will be almost white when it leaves the second kier containing the resinate of soda; it will therefore require very little decolourising. If the goods have been printed on, more chloride will be needed. The cloth should lie from two to eight hours in the liquor, or after saturation with it. The action is quickened if warmth is used. They are soured then, as before, in muriatic and sulphuric acid, at 2° Tw., for three or four hours; then wash for drying.

From what has been said, it will be seen that the operations of the bleacher are not so numerous as at first sight appears, when we call every washing a separate process; and although it really is so, it is managed so rapidly that it can scarcely be said to occupy time, and as it is carried on at the same time as the other processes, it scarcely can be said to give trouble. The work may be divided into:—

1. Singeing. 2. Bowking with lime. 3. Washing, souring, and washing. 4. Bowking with resinate of soda. 5. Washing and chlorinating. 6. Souring, washing, and drying.

Bleaching of Linen.

Linen contains much more colouring matter than cotton. The former loses nearly a third of its weight, while the latter loses not more than a twentieth. The fibres of flax possess, in the natural condition, a light grey, yellow, or blond colour. By the operation of rotting, or, as it is commonly called, water-retting, which is employed to enable the textile filaments to be separated from the boon, or woody matter, the colour becomes darker, and, in consequence probably of the putrefaction of the green matter of the bark, the colouring substance appears. Hence, flax prepared without rotting is much paler, and its colouring matter may be in a great measure removed by washing with soap, leaving the filaments nearly white. Mr. James Lee obtained a patent in 1812, as having discovered that the process of steeping and dew-retting is unnecessary, and that flax and hemp will not only dress, but will produce an equal if not greater quantity of more durable fibre, when cleaned in the dry way. Mr. Lee stated that, when hemp or flax plants are ripe, the farmer has nothing more to do than to pull, spread, and dry them in the sun, and then to break them by proper machinery. This promising improvement has apparently come to nought, having been many years abandoned by the patentee himself, though he was favoured with a special Act of Parliament, which permitted the specification of his patent to remain sealed up for seven years, contrary to the general practice in such cases.

The substance which gives steeped flax its peculiar tint is insoluble in boiling water, in acids, and in alkalis; but it possesses the property of dissolving in caustic or carbonated alkaline lyes, when it has by previous exposure been acted on only by chlorine. This process is effected in great measure by the influence of air in combination with light and moisture acting on the linen cloth laid upon the grass: but chlorine hastens the operation. In no case, however, is it possible to dissolve the colour completely at once, but there must be many alternate exposures to oxygen or chlorine, and alkali, before the flax becomes white. It is this circumstance alone which renders the bleaching of linen an apparently complicated business.

Old Method. — A parcel of goods consists of 360 pieces of those linens which are called Britannias. Each piece is 35 yards long, and weighs, on an average, 10 lbs.; the weight of the parcel is, in consequence, about 3600 lbs. avoirdupois weight. The linens are first washed, and then steeped in waste alkaline lye, as formerly described under these processes; they then undergo the following operations: —

1. Bucked with 60 lbs. pearl-ashes, washed, exposed on the field.
2. Ditto 80 ditto ditto ditto ditto.
3. Ditto 90 potashes ditto ditto ditto.
4. Ditto 80 ditto ditto ditto ditto.
5. Ditto 80 ditto ditto ditto ditto.
6. Ditto 50 ditto ditto ditto ditto.
7. Ditto 70 ditto ditto ditto ditto.
8. Ditto 70 ditto ditto ditto ditto.
9. Soured one night in dilute sulphuric acid; washed.
10. Bucked with 50 lbs. pearl-ashes, washed, exposed on the field.
11. Immersed in the chloride of potash or lime 12 hours.
12. Boiled with 30 lbs. pearl-ashes, washed, exposed on the field.
13. Ditto 30 ditto ditto ditto ditto.
14. Soured, washed.

The linens are then taken to the rubbing-board, and well rubbed with a strong lather of black soap, after which they are well washed in pure spring water. At this period they are carefully examined, and those which are fully bleached are laid aside to be blued, and made up for the market; while those which are not fully white are returned to be boiled, and steeped in the chloride of lime or potash; then soured, until they are fully white.

By the above process, 690 lbs. weight of alkali is taken to bleach 360 pieces of linen, each piece consisting of 35 yards in length; so that the expenditure of alkali would be somewhat less than 2 lbs. for each piece, were it not that some parts of the linens are not fully whitened, as above noted. Two pounds of alkali may therefore be stated as the average quantity employed for bleaching each piece of goods.

What is called the old method, or that used from about the introduction of bleaching powder, at the beginning of the century, till within ten or fifteen years, required bleaching on the grass; and the mode in which it was managed in Ireland and Scotland, where it held its ground longest, is as follows: —

1. They were rot-steeped in a weak solution of potash, at about 130° F., for two days, until the dressing used in manufacturing the cloth was removed.
2. Washed.

Digitized by Google

3. Boiled or bowked in potash lye, at ¼° Twaddle, for ten hours.
4. Washed, and the ends turned so that the whole might be equally exposed to the ley.
5. Boiled or bowked in a similar lye to the above for twelve hours.
6. Washed well.
7. Exposed on the grass for three days, and watered.
8. Taken up and soured with sulphuric acid, at 2° Tw., for four hours.
9. Taken up and washed well.
10. Boiled again for eight hours in potash lye, at 1° Tw., to which had been added black or soft soap, about 20 lbs. to a kier of about 300 gallons.
11. Washed.
12. Crofted, or exposed on the grass, as before.
13. Treated with chloride of lime at 1½° Tw., for four hours.
14. Washed.
15. Soured in sulphuric acid, at 2° Tw., for four hours.
16. Washed.
17. Boiled for six or seven hours with soap and lye, using in this case more soap and one-third less lye than in the former bowkings.
18. Drawn out and put through rub-boards. This is a kind of washing machine, made of blocks of wood, with hard-wood teeth. The goods are washed by it in a soapy liquid. The teeth moving rapidly, drive the soap into the cloth.
19. Boiled in the lye alone for six hours.
20. Washed.
21. Crofted, keeping them very clean, as this is the last exposure.
22. Treated with chloride of lime.
23. They are then starched, blued, and beetled, to finish them for the market. These operations last six weeks.

New System, as practised in Scotland and Ireland.—Directions given by an extensive Bleacher.

1. Wash.
2. Boil in lime water ten or twelve hours.
3. Sour in muriatic acid, of 2° Tw., for three, four, or five hours.
4. Wash well.
5. Boil with resin and soda-ash twelve hours.
6. Turn the goods, so that those at the top shall be at the bottom, and boil again as at No. 5.
7. Wash well.
8. Chemick, at ¼° Tw., or 1002·5, four hours.
9. Sour, at 2° Tw., or 1010° specific gravity.
10. Wash.
11. Boil in soda-ash ten hours.
12. Chemick again.
13. Wash and dry.

This is the system chiefly adopted when the goods are to be printed.

The following is the system practised in the neighbourhood of Perth, where the chief trade is in plain sheetings:—

1. Before putting them into operation, they are put up into parcels of about 35 cwts.
2. They are then steeped in lye for twenty-four hours.
3. Then washed and spread on the grass for about two days.
4. Boiled in lime water.
5. Turned, and boiled again in lime water, those at the top being put at the bottom. 60 lbs. of lime are used at a time, and about 600 gallons of water.
6. Washed, then soured in sulphuric acid of 2° Tw., or 1010° sp. gr., for four hours, then washed again.
7. Boiled with soda-ash for ten hours; 110 lbs. used.
8. Washed and spread out on the green, or crofted.
9. Boiled again in soda as before.
10. Crofted for three days.
11. They are then examined: the white ones are taken out; those that are not finished are boiled and crofted again.
12. Next, they are scalded in water containing 80 lbs. of soda-ash, and washed.
13. The chloride of lime is then used at ¼° Tw., or 1002·5 specific gravity.
14. Washed and scalded.
15. Washed and treated with chloride of lime.
16. Soured, for four hours, with sulphuric acid, at 2° Tw., or 1010° specific gravity
17. Washed.

Digitized by Google

If cloths lighter than sheetings are used, the washing liquids are used weaker. The great point is to observe them carefully during the process, in order to see what treatment will suit them best.

It will be seen that the process of bleaching linen is still very tedious; and although it may be managed in a fortnight, it is seldom that this occurs regularly for a great length of time. The action of the light introduces at once an uncertain element, as this varies so much in our climate. If, again, linen be long exposed to the air in a moist condition, it is apt to become injured in strength. To shorten the process, therefore, is important; and if no injurious agents are introduced, a shortening promises also to give increased strength to the fibre. It has not been found possible to introduce chlorine into linen bleaching at an early stage, as in the case of cotton; and the processes for purifying it without any chlorine render it so white that unskilled persons would call it as white as snow. The chlorine is introduced nearly at the end of the operation, after a series of boilings with alkalis, sourings, and exposures on the grass. If introduced at an earlier stage, the colour of the raw cloth becomes fixed, and cannot be removed. The technical term for this condition is "*set.*" Mr. F. M. Jennings, of Cork, has just patented a method which promises to obviate the difficulty. The peculiarity consists in using the alkali and the chloride of alkali at the same moment, thus giving the alkali opportunity to seize on the colouring matter as soon as the chloride has acted, and thereby preventing the formation of an insoluble compound. He prefers the chlorides of potash or soda. His plan is as follows:—

1. He soaks the linen in water for about twelve hours, or boils it in lime or alkali, or alkali with lime, and then soaks it in acid, as he uses soaps of resin in other mixtures—the alkalis being from 3° to 5° Tw., 1015°—1025° specific gravity.
2. Boils in a similar alkaline solution.
3. Washes.
4. Puts it into a solution of soda, of 5° Tw., 1025° specific gravity, adding chloride of soda until it rises up to from 6°–7° Tw. It is allowed to remain in this solution for some hours, and it is better if subjected to heating or squeezing between rollers, as in the washing machine.
5. He then soaks, sours, and washes.
6. He then puts it a second time into the solution of alkali and chloride.
7. Then washes, and boils again with soda. These operations, 6 and 7, may be repeated until the cloth becomes almost white.

The amount of exposure on the grass by this process is said to be not more than from one-half to one-fourth that required by the nsual method, or it may be managed so as entirely to supersede crofting.

Chevalier Claussen has opened up the filaments of flax by the evolution of gas from a carbonate in which the plant is steeped, and at the same time bleached by chloride of magnesia, but this has not been successful.

Bleaching of Silk.

Silk in its raw state, as spun by the worm, is either white or yellow of various shades, and is covered with a varnish which gives it stiffness and a degree of elasticity. For the greater number of purposes to which silk is applied, it must be deprived of this native covering, which was long considered to be a sort of gum. The operation by which this colouring matter is removed is called scouring, cleansing, or boiling. A great many different processes have been proposed for freeing the silk fibres from all foreign impurities, and for giving it the utmost whiteness, lustre, and pliancy; but none of the new plans has superseded, with any advantage, the one practised of old, which consists essentially in steeping the silk in a warm solution of soap; a circumstance placed beyond all doubt by the interesting experiments of M. Roard. The alkalis, or alkaline salts, act in a marked manner upon the varnish of silk, and effect its complete solution; the prolonged agency even of boiling water or soap and water destroys the brilliancy of silk. It would appear, however, that the Chinese do not employ this method, but something that is preferable. Probably the superior beauty of their white silk may be owing to the superiority of the raw material.

The most ancient method of scouring silk consists of three operations. For the first, or the *ungumming*, thirty per cent. of soap is dissolved in clean water at a boiling heat; then the temperature is lowered by the addition of a little cold water, by withdrawing the fire, or at least by damping it. The hanks of silk suspended upon horizontal poles over the boiler are now plunged into the soapy solution, kept at a heat somewhat under ebullition, which is an essential point; for, if hotter, the soap would attack the substance of the silk, and not only dissolve a portion of it, but deprive the whole of its lustre. The portions of the hanks plunged in the

Digitized by Google

bath get scoured by degrees; the varnish and the colouring matter are removed, and the silk assumes its proper whiteness and pliancy. Whenever this point is attained, the hanks are turned round upon the poles, so that the portion formerly in the air may be also subjected to the bath. As soon as the whole is completely ungummed, they are taken out, wrung by the peg, and shaken out; after which, the next step, called the *boil*, is commenced. About 25 lbs. or 35 lbs. of ungummed silk are enclosed in bags of coarse canvas, called *pockets*, and put into a similar bath with the preceding, but with a smaller proportion of soap, which may therefore be raised to the boiling point without any danger of destroying the silk. The ebullition is to be kept up for an hour and a half, during which time the bags must be frequently stirred, lest those near the bottom should suffer an undue degree of heat. The silk experiences in these two operations a loss of about 25 per cent. of its weight.

The third and last scouring operation is intended to give the silk a slight tinge, which renders the white more agreeable, and better adapted to its various uses in trade. In this way we distinguish the China white, which has a faint cast of red, the silver white, the azure white, and the thread white. To produce these different shades, we begin by preparing a soap-water so strong as to lather by agitation; we then add to it, for the China white, a little arnotto, mixing it carefully in; and then passing the silk properly through it, till it has acquired the wished-for tint. As to the other shades, we need only azure them more or less with a fine indigo, which has been previously washed several times in hot water, and reduced to powder in a mortar. It is then diffused through boiling water, allowed to settle for a few minutes, and the supernatant liquid, which contains only the finer particles, is added to the soap bath, in such proportion as may be requisite. The silk, on being taken out of this bath, must be wrung well, and stretched upon perches to dry; after which it is introduced into the sulphuring chamber, if it is to be made use of in the white state. At Lyons, however, no soap is employed at the third operation; after the boil, the silk is washed, sulphured, and azured, by passing through very clear river water properly blued.

The present practice in the silk-works in Lancashire is as follows:—

The Italian silk arrives in this country with a little soap in it, put in by the throwsters there, amounting to one drachm to a pound of silk. It is received here in hanks, and bleached in that state. The hanks are hung on sticks or small poles, about three pounds of silk being on each stick. The sticks being laid across a vessel, the silk hangs down, and in this way may be immersed in any liquid. The treatment of silk is then much more tender than that of cotton.

1. The hot lather is made with 3 lbs. of soap in 50 gallons of water; to this is added 1 lb. of soda crystals. The silk is kept in this lather at a temperature of from 175° to 190° F. for three quarters of an hour. It is then wrung or dried in the hydro-extractor (called hydro or whizzer in Lancashire works). 2. It is then, for the purpose of straightening it, rolled on a cocoa-nut roll-pin 4 in. in diameter, a little turn being given it occasionally, by the finger and thumb, to prevent entangling. 3. It is then put into bags of one yard square. The hanks are laid flat, and the bags stitched down. In this state they are boiled for 3½ hours, using for the same amount of water as before, 3 lbs. of soap to 20 lbs. of silk. 4. The silk is then washed or moved about by the hand in a cistern one yard wide and one deep, retaining as much soap as will make a pretty permanent lather. To this there is generally added a small quantity of archil, about ¼ oz. to 4 lbs. of silk. 5. It is then dried in the hydro-extractor. 6. It is then straightened and sulphured. The sulphuring is done in a small apartment, which should be very high. The size is frequently 10 feet square by 20 in height. The silk is hung up in it, and 4 lbs. of sulphur for each 40 lbs. of silk are put on the floor and set fire to. The room is closed as well as possible, and the silk is allowed to remain 4 hours. This is the bleaching, and it requires now only to be washed by rinsing three to four times in cold water. A little indigo blue is used to give it a pearly appearance. The use of archil, which has been mentioned, depends upon the shade of white, so to speak, which is wanted. 7. The silk is now dried by the hydro-extractor first, and then by exposing to a temperature of 85—90°. If heavily laden with gums, silk must be dried at a still cooler temperature. In this operation of bleaching, 1 lb. of good silk loses 4 oz.; but as it seldom arrives very pure, the usual loss to the pound of silk is 5 oz.

The first, or simmering, operation mentioned here, is not necessary for the white silk of China.

The silks intended for the manufacture of blondes and gauzes are not subjected to the ordinary scouring process, because it is essential, in these cases, for them to preserve their natural stiffness. We must therefore select the raw silk of China, or the whitest raw silks of other countries; steep them, rinse them in a bath of pure water, or in one containing a little soap; wring them, expose them to the vapour of

Digitized by Google

sulphur, and then pass them through the azure water. Sometimes this process is repeated.

Before the memoir of M. Roard appeared, extremely vague ideas were entertained about the composition of the native varnish of silk. He has shown that this substance, so far from being of a gummy nature, as had been believed, may be rather compared to bees' wax, with a species of oil and a colouring matter which exist only in raw silks. It is contained in them to the amount of from 23 to 24 per cent., and forms the portion of weight which is lost in the *ungumming*. It possesses, however, some of the properties of vegetable gums, though it differs essentially as to others. In a dry mass, it is friable and has a vitreous fracture; it is soluble in water, and affords a solution which lathers like soap; but when thrown upon burning coals, it does not soften like gum, but burns with the exhalation of a fetid odour. Its solution, when left exposed to the open air, is at first of a golden yellow, becomes soon greenish, and ere long putrefies, as a solution of animal matter would do in similar circumstances. M Roard assures us that the city of Lyons alone could furnish several thousand quintals of this substance *per annum*, were it applicable to any useful purpose.

The yellow varnish is of a resinous nature, altogether insoluble in water, very soluble in alcohol, and contains a little volatile oil, which gives it a rank smell. The colour of this resin is easily dissipated, either by exposure to the sun or by the action of chlorine: it forms about one fifty-fifth of its weight.

Bees' wax exists also in all the sorts of silk, even in that of China; but the whiter the filaments, the less wax do they contain.

M. Roard has observed that, if the silk be exposed to the soap-baths for some time after it has been stripped of its foreign matters, it begins to lose body, and has its valuable qualities impaired. It becomes dull, stiff, and coloured in consequence of the solution, more or less considerable, of its substance; a solution which takes place in all liquids, and even in boiling water. It is for this reason that silks cannot be alumed with heat; and that they lose some of their lustre in being dyed brown, a colour which requires a boiling hot bath. The best mode, therefore, of avoiding these inconveniences, is to boil the silks in the soap-bath no longer than is absolutely necessary for the scouring process, and to expose them in the various dyeing operations to a temperature as moderate as may be sufficient to communicate the colour. When silks are to be dyed, much less soap should be used in the cleansing, and very little for the dark colours. According to M. Roard, raw silks, white or yellow, may be completely scoured in one hour, with 15 lbs. of water for one of silk, and a suitable proportion of soap. The soap and the silk should be put into the bath half an hour before its ebullition, and the silk should be turned about frequently. The dull silks, in which the varnish has already undergone some alteration, never acquire a fine white until they are exposed to sulphurous acid gas. Exposure to light has also a very good effect in whitening silks, and is had recourse to, it is said, with advantage, by the Chinese.

Baumé contrived a process which does not appear to have received the sanction of experience, but which may be a guide in the right way. He macerates the yellow raw silk in a mixture of alcohol at 36° (sp. gr. 0837) and one thirty-second part of pure muriatic acid. At the end of forty-eight hours, it is as white as possible, and the more so, the better the quality of silk. The loss which it suffers in this menstruum is only one fortieth; showing that nothing but the colouring matter is abstracted. The expense of this menstruum is the great obstacle to Baumé's process. The alcohol, however, might be in a very great measure recovered, by saturating the acid with chalk, and redistillating.

Bleaching of Wool.

Wool, like the preceding fibrous matter, is covered with a peculiar varnish, which impairs its qualities, and prevents it from being employed in the raw state for the purposes to which it is well adapted when it is scoured. The English give the name *yolk*, and the French *suint*, to that native coat: it is a fatty unctuous matter, of a strong smell, which apparently has its chief origin in the cutaneous perspiration of the sheep; but which, by the agency of external bodies, may have undergone some changes which modify its constitution. It results from the experiments of M. Vauquelin, that the *yolk* is composed of several substances; namely, 1, a soap with basis of potash, which constitutes the greater part of it; 2, of a notable quantity of acetate of potash; 3. of a small quantity of carbonate, and a trace of chloride of potassium; 4, of a little lime in an unknown state of combination; 5, of a species of sebaceous matter, and an animal substance to which the odour is due. There are several other accidental matters present on sheep's wool.

The proportion of yolk is variable in different kinds of wool, but in general it is

Digitized by Google

more abundant the finer the staple; the loss by scouring being 45 per cent. for the finest wools, and 35 per cent. for the coarse.

The yolk, on account of its soapy nature, dissolves readily in water, with the exception of a little free fatty matter, which easily separates from the filaments, and remains floating in the liquor. It would then appear sufficient to expose the wools to simple washing in a stream of water; yet experience shows that this method never answers so well as that usually adopted, which consists in steeping the wool for some time in simple warm water, or in warm water mixed with a fourth of stale urine. From 15 to 20 minutes of contact are sufficient in this case, if we heat the bath as warm as the hand can bear it, and stir it well with a rod. At the end of this time the wool may be taken out, set to drain, then placed in large baskets, in order to be completely rinsed in a stream of water.

It is generally supposed that putrid urine acts on the wool by the ammonia which it contains, and that this serves to saponify the remainder of the fatty matter not combined with the potash, although M. Vauquelin gave another opinion. Fresh urine contains a free acid, which, by decomposing the potash soap of the yolk, counteracts the scouring operation.

If wools are better scoured in a small quantity of water than in a great stream, we can conceive that this circumstance must depend upon the nature of the yolk which, in a concentrated solution, acts like a saponaceous compound, and thus contributes to remove the free fatty particles which adhere to the filaments. It should also be observed that too long a continuance of the wool in the yolk water, hurts its quality very much, by weakening its cohesion, causing the filaments to swell, and even to split. It is said then to have lost its *nerve*. Another circumstance in the scouring of wool, that should always be attended to, is never to work the filaments together to such a degree as to occasion their felting; but in agitating we must merely push them slowly round in the vessel, or press them gently under the feet. Were it at all felted, it would neither card nor spin well.

As the heat of boiling water is apt to decompose woollen fibres, we should be careful never to raise the temperature of the scouring bath to near this point, nor, in fact, to exceed 140° F. Some authors recommend the use of alkaline or soapy baths for scouring wool, but practical people do not deviate from the method above described.

When the washing is completed, all the wool which is to be sent white into the market, must be exposed to the action of sulphurous acid, either in a liquid or a gaseous state. In the latter case, sulphur is burned in a close chamber, in which the wools are hung up or spread out; in the former, the wools are plunged into water moderately impregnated with the acid. (See SULPHURING.) Exposure on the grass may also contribute to the bleaching of wool. Some fraudulent dealers are accused of dipping wools in butter-milk, or chalk and water, in order to whiten them and increase their weigh.

Wool is sometimes whitened in the fleece, and sometimes in the state of yarn; the latter affording the best means of operating. It has been observed that the wool cut from certain parts of the sheep, especially from the groin, never bleaches well.

After sulphuring, the wool has a harsh crispy feel, which may be removed by a weak soap-bath. To this also the wool-comber has recourse when he wishes to cleanse and whiten his wools to the utmost. He generally uses a soft or potash soap, and after the wool is well soaked in the warm soap-bath, with gentle pressure he wrings it well with the help of a hook, fixed at the end of his washing tub, and hangs it up to dry.

The actual operations of purifying wool are so blended with the methods of weaving and working it, that, to show it fully, I shall give here the process of preparing flannels, out of which the parts relating to cleansing may be taken.

1. The wool is weighed out into parcels of 120 lbs. Add, on an average, 20 to 21 lbs. or 10 quarts of oil—rape oil or olive, or mixed, or, as is very common now, oleic acid, which may be so used as not to be hurtful to the machinery in this condition. This was introduced by Mr. M'Dougall.

2. It is then devilled or willowed, carded, slubbed, and spun.

The warp portion is made at this stage if wanted.

3. Scoured in the warp with urine and hot water, occasionally using a little ammonia.

4. Sized with a mineral sizing, and put into the looms.

5. If spun for weft, it is soaked, when on the bobbin, with cold water in a cistern, an air-pump being used to extract the air from the threads and to compel the water to enter.

6. The water is then removed by a revolving water-extractor. This process leaves the weft full and soft.

Digitized by Google

Skin wool, so called, is taken from the skin by means of lime, which makes the oil stiff, forming a compound.

7. The piece being now woven is grey. It is sent to the finishing or fulling mill, sprinkled over with urine and pigs' dung, and put under the fulling hammers until equally wet.

8. It is then washed out or scoured with cold water, raised with teasels, dried out of doors or in a stove.

Treated a little differently, accordingly as Welsh or Lancashire is wanted.

9. It is then sprinkled again with soap-and-water, and milled one to two hours in the fulling stock.

Three quarters to 1 lb. of soap is given for each piece.

10. Cleared with cold water.

11. Hung up wet in a sulphur stove, several pots of sulphur lighted. The door is shut till morning. Washed four to six hours in cold water, treated with finely-ground indigo, dried, and a little further raised, pressed, and rolled up for sale.

If the flannel is Welsh, it is dried and sprinkled with fullers' earth (instead of the soap-and-water used for the Lancashire), well milled for some time, and then cleared in cold water. It is then put into a cistern filled with water, having some soap thrown in as well as a few cakes of Prussian blue. This dipping is repeated three or four times, and between each the flannel is milled in the fulling stock. This levels the colour. When blue enough, the pieces are dried and made up for sale.

It appears that Welsh flannel is not sulphured; the cleaning is done entirely by ammonia.

Sulphuring.—In the usual mode of sulphuring the cloth is hung on pegs or rails in rooms which are called the sulphur chambers or stoves. An iron pot containing sulphur is placed in each corner of the room, and the sulphur inflamed. The door is then shut and clayed. By the morning the process is finished, and the door is opened. This mode is objected to, because the sulphur, not being properly burnt, lodges in the cloth, and acts injuriously on it in the processes of dyeing or printing. Sparks also are apt to rise up and injure the pieces, the sulphur not being pure, and burning irregularly. Drops also of water impregnated strongly with sulphurous acid are apt to fall from the roof, doing injury to the cloth.

To avoid these inconveniences Mr. Thom has invented a method by which the cloth is rapidly carried through the sulphuring chamber, and subjected to the influence of the vapour on the principle of the washing machine. A great deal of time and space is of course saved; it is on the same principle as the washing apparatus, vapour being used instead of water. This has not yet been applied to thick woollen. See CALICO PRINTING.

BLEACHING OF MATERIALS FOR PAPER.

The bleaching of paper is conducted on the same principle as the bleaching of cotton. Paper is made principally of two materials, cotton and flax, generally mixed. The cotton waste of the mills, which is that inferior portion which has become too impure for spinning, or otherwise deteriorated, and cotton rags are the principal, if not the only, sources of the cotton used by paper makers. The waste is sorted by hand, the hard and soft being separated, and all accidental mixtures which occur in it are removed. This is done at first roughly on a large lattice, which is a frame of wire cloth, having squares of about three-quarters of an inch through which impurities may fall. It is then put into a duster, which is a long rectangular box, it may be ten feet long, lying horizontally, the inside diameter about two feet, and covered with wire gratings running horizontally, leaving openings of half an inch in width. As this revolves, the waste is thrown from one angle to the other, and throws out whatever dust or other material falls into the holes or spaces. The fibrous matter has little tendency to separate from the mass, which is somewhat agglutinated by being damp, chiefly from the oil obtained during the processes in the cotton mill. A second duster, however, is used to retain whatever may be of value; it is a kind of riddle. It is then transferred to the lattices, which are a series of boxes covered with wire gauze, the meshes of which are about half an inch square, and so arranged as to form a series of sorting tables. The sorting generally is done by young women. Each table has a large box or basket beside it, into which the sorted material is thrown; this is removed when filled, by being pushed along a railroad or tramway. Pieces of stone, clay, leather, wood, nails, and other articles, are taken out. The cotton is then put into a devil similar to that which is used in cotton machinery, but having larger, stronger teeth, which tear it up into small fragments.

The rags are sorted according to quality, woollen carefully removed, and all the unavailable material sent back to the buyer. They are then chopped up by a knife,

Digitized by Google

on the circumference of a heavy wheel, into pieces of an inch wide, devilled, and dusted.

The rags and the cotton waste are bleached in a similar manner. The cotton is put into kiers of about ten feet in diameter, of a kind similar to those described, and boiled with lime. The amount of lime used is about 6 lbs. to a cwt. of of cotton or rags, but this varies according to the impurity. The lime removes a great amount of impure organic matter, and, as in bleaching, cotton cloth lays hold of the fatty matter, of which there is a great deal in the waste. When taken out, it is allowed to lie from two or three hours. The appearance is not much altered; it appears as impure as ever.

It is then put into the rag-engine and washed clean. This is a combined washing machine and filter, the invention of Mr. Wrigley, near Bury. The washing may last an hour and a half, or more. See PAPER.

The cotton has now a bright grey colour, and looks moderately clean. It is full of water, which is removed by a hydraulic press, the cotton being put into an iron cylindrical box with perforated sides. It is then boiled in kiers or puffing boilers, where soda-ash is used, at the rate of 4 to 5 lbs. a cwt. Only as much water is used as will moisten the goods thoroughly. Much water would weaken the solution and render more soda necessary. It is then washed again in the rag-engine; afterwards put into chloride of lime, acidified as in cotton bleaching, and washed again in the rag-engine.

The cotton rags are treated in a similar manner. The coloured rags are treated separately, requiring a different treatment according to the amount of colour; this consists chiefly in a greater use of chloride of lime.

Some points relating to bleaching are necessarily treated of under CALICO PRINTING.

BLEACHING POWDER. Chloride of Lime (*which see*).

BLEAK. (*Cyprinus alburnus.*) The scales of this fish are used for making the essence of pearl, or *essence d'orient*, with which artificial pearls are manufactured. In the scales of the fish the optical effect is produced in the same manner as in the real pearl, the grooves of the latter being represented by the inequalities formed by the margins of the concentric laminæ of which the scales are composed. These fish are caught in the Seine, the Loire, the Saone, the Rhine, and several other rivers. They are about four inches in length, and are sold very cheap after the scales are washed off. It is said that 4000 fish are necessary for the production of a pound of scales, for which the fishermen of the Chalonnois get from 18 to 25 livres.

The pearl essence is obtained merely by well washing the scales which have been scraped from the fish in water, so as to free them from the blood and mucilaginous matter of the fish. See PEARLS, ARTIFICIAL.

BLENDE, from *Blenden*, Germ. to dazzle. Sulphide or sulphuret of zinc, is a common ore of zinc, composed of zinc 67, sulphur 33; but it usually contains a certain proportion of the sulphide of iron, which imparts to it a dark colour, whence the name of "Black Jack," applied to it by the Cornish miner. The ore of this country generally consists of zinc 61·5, iron 4·0, sulphur 33·0. Blende occurs either in a botryoidal form or in crystals (often of very complex forms), belonging to the tetrahedal division of the monometric system. H = 3·5 to 4. Specific gravity = 3·9 to 4. See ZINC.—H. W. B.

In some districts the presence of the sulphide of zinc is regarded by the miners as a favourable indication, hence we have the phrase, "*Black Jack rides a good horse.*" In other localities it is thought to be equally unfavourable, and the miners say, "*Black Jack cuts out the ore.*" For many years the English zinc ores were of little value, the immense quantity of zinc manufactured by the Vieille Montagne company, and sent into this country, being quite sufficient to meet the demand. Beyond this, there was some difficulty in obtaining zinc which would roll into sheets, from English sulphides.

Most of the zinc obtained from blende is used in the manufacture of brass. Dana has given the following analyses of varieties of blende:—

	Sulphide of Zinc.	Sulphide of Iron.
Charente - - - - - - -	82·76	13·71
English - - - - - - -	91 8	6·4

Pure blende is a mineralogical rarity; the white and colourless variety of New Jersey, United States, was analysed by the late T. H. Henry, and found to be absolutely pure, with the exception of a trace of cadmium. Blende nearly always contains sulphide of iron. In 13 out of 16 analyses of blende from different localities recorded by Rammelsberg, iron is present in proportions varying from 1·18 to

Digitized by Google

18·1 per cent. Copper occasionally occurs in blende, but rarely above 1 per cent. Cadmium is a frequent, if not a general constituent of blende. The blende from the King William mine at Clausthal contains, according to Kuhlemann, 0·63 per cent. of antimony, 0·79 of cadmium, and 0·13 of copper, besides 1·18 of iron. Blende is met with in association with galena. Iron pyrites and copper pyrites, from which it should be dressed as clean as possible, although in this there is some difficulty, owing to the very close approximation of the specific gravities of these ores. Blende is occasionally argentiferous, and sometimes sufficiently so to allow of the profitable extraction of the silver. In one of the mines in the Chiverton district, near Truro, Cornwall, some very fine examples of this argentiferous blende has been discovered. In one of the zinc ores of Silesia, the new metal INDIUM has been discovered by the aid of spectrum analysis. See INDIUM. Plattner states that blende occasionally contains traces of tin and manganese. (*Percy's Metallurgy.*) The red varieties of blende often contain from 2 to 3 per cent. of sulphide of cadmium, especially that which is found at Marmato, near Popayan (see MARMATITE.) Dana has given the following analyses of varieties of Blende.

BLEU DE LYON. See ANILINE BLUE.

BLEU DE PARIS. See ANILINE BLUE.

BLISTERED COPPER ORE. A botryoidal variety of copper pyrites, which has been found at the copper mines in the neighbourhood of Camborne, in remarkably fine masses. Of late years it has been but rarely found in those mines. See COPPER.

BLISTER-STEEL. Bars of steel which exhibit blister-like protuberances. These blisters have been supposed by some to be due to the presence of silicon or carbon in a gaseous state, but this is very doubtful. The question still requires careful investigation. See STEEL.

BLIND COAL, a name given to ANTHRACITE (*which see*).

BLOCK MANUFACTURE. Though the making of ships' blocks belongs rather to a dictionary of engineering than of manufactures, it may be expected that some account should be given of the automatic machinery for making blocks, so admirably devised and mounted by Sir M. I. Brunel, for the British Navy, in the dockyard of Portsmouth.

The series of machines and operations are as follows:—

1. *The straight cross-cutting saw.*—The log is placed horizontally on a very low bench, which is continued through the window of the mill into the yard. The saw is exactly over the place where the log is to be divided. It is let down, and suffered to rest with its teeth upon the log, the back still being in the cleft of the guide. The crank being set in motion, the saw reciprocates backwards and forwards with exactly the same motion as if worked by a carpenter, and quickly cuts through the tree. When it first begins to cut, its back is in the cleft in the guide, and this causes it to move in a straight line; but before it gets out of the guide, it is so deep in the wood as to guide itself; for in cutting across the grain of the wood, it has no tendency to be diverted from its true line by the irregular grain. When the saw has descended through the tree, its handle is caught in a fixed stop, to prevent its cutting the bench. The machine is thrown out of gear, the attendant lifts up the saw by a rope, removes the block cut off, and advances the tree to receive a fresh cut.

2. *The circular cross-cutting saw.*—This saw possesses universal motion; but the axis is always parallel to itself, and the saw in the same plane. It can be readily raised or lowered, by inclining the upper frame on its axis; and to move it sidewise, the saw frame must swing sidewise on its joints which connect it with the upper frame. These movements are effected by two winches, each furnished with a pair of equal pinions, working a pair of racks fixed upon two long poles. The spindles of these winches are fixed in two vertical posts, which support the axis of the upper frame. One of these pairs of poles is jointed to the extreme end of the upper frame; therefore, by turning the handle belonging to them, the frame and saw are elevated or depressed; in like manner, the other pair is attached to the lower part of the saw frame, so that the saw can be moved sidewise by means of their handles, which then swing the saw from its vertical position.

These two handles give the attendant a complete command of the saw, which we suppose to be in rapid motion, the tree being brought forward and properly fixed. By one handle, he draws the saw against one side of the tree, which is thus cut into (perhaps half through); now, by the other handle, he raises the saw up, and by the first-mentioned handle he draws it across the top of the tree, and cuts it half through from the upper side; he then depresses the saw and cuts half through the next side; and lastly a trifling cut of the saw, at the lower side, completely divides the tree, which is then advanced to take another cut.

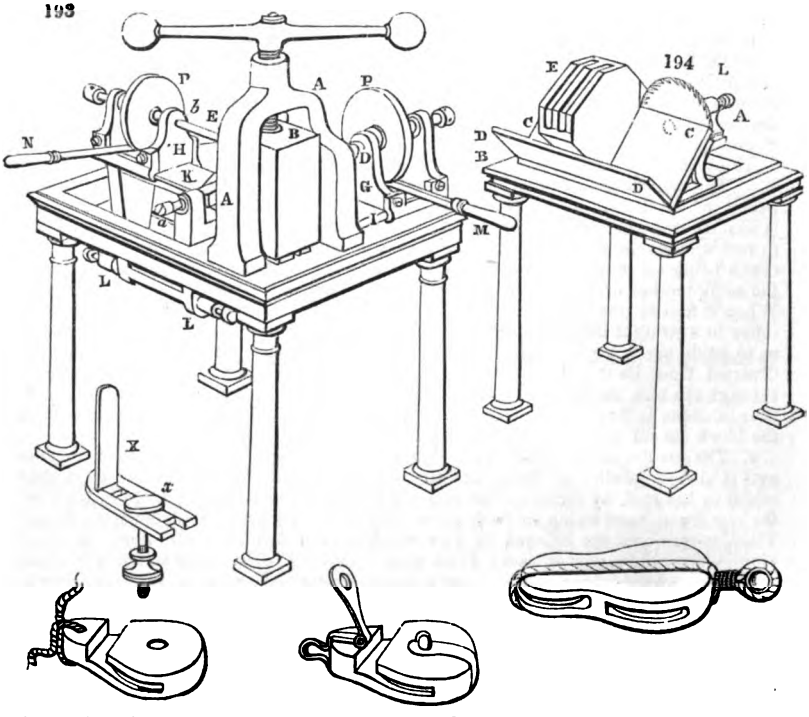
The great reciprocating saw is on the same principle as the saw mill in common use in America.

3. *The circular ripping saw* is a thin circular plate of steel, with teeth similar to those of a pit saw, formed in its periphery. It is fixed to a spindle placed horizontally, at a small distance beneath the surface of a bench or table, so that the saw projects a few inches above the bench through a crevice. The spindle being supported in proper collars has a rapid rotatory motion communicated to it by a pulley on the opposite end, round which an endless strap is passed from a drum placed overhead in the mill. The block cut by the preceding machine from the end of the tree is placed with one of the sides flat upon the bench, and thus slides forward against the revolving saw, which cuts the wood with a rapidity incredible to anyone who has not seen these or similar machines.

4. *Boring machine.*—The blocks prepared by the foregoing saws are placed in the machine represented in *fig.* 193. This machine has an iron frame, A A, with three legs, beneath which the block is introduced, and the screw near B being forced down upon it, confines it precisely in the proper spot to receive the borers D and E. This spot is determined by a piece of metal fixed perpendicularly just beneath the point of the borer E, shown separately on the ground at X; this piece of metal adjusts the position

Digitized by Google

for the borer D, and its height is regulated by resting on the head of the screw *x*, which fastens the piece X down to the frame. The sides of the block are kept in a parallel position, by being applied against the heads of three screws tapped into the double leg of the frame A. The borer D is adapted to bore the hole for the centre pin in a direction exactly perpendicular to the surface resting against the three screws; the other, at E, perforates the holes for the commencement of the sheave holes. Both borers are constructed in nearly the same manner; they are screwed upon the ends of small mandrels, mounted in frames similar to a lathe. These frames, G and H, are



fitted with sliders upon the angular edges of the flat broad bars, I and K. The former of these is screwed fast to the frame; the latter is fixed upon a frame of its own, moving on the centre screws at L L, beneath the principal frame of the machine. By this means the borer E can be moved within certain limits, so as to bore holes in different positions. These limits are determined by two screws, one of which is seen at *a*; the other being on the opposite side is invisible. They are tapped through fixed pieces projecting up from the frame. A projecting piece of metal, from the under side of the slider K of the borer E, stops against the ends of these screws, to limit the excursion of the borer. The frames for both borers are brought up towards the block by means of levers M and N. These are centred on a pin, at the opposite sides of the frame of the machine, and have oblong grooves through them which receive screw pins, fixed into the frames G and H, beneath the pulleys P P, which give motion to the spindles.

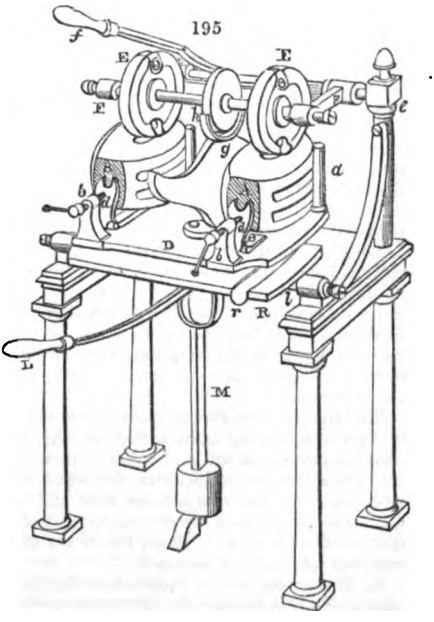
5. *The mortising machine* is a beautiful piece of mechanism, but too complicated for description within the limits prescribed to this article.

The corner saw, *fig.* 194, consists of a mandrel mounted in a frame A, and carrying a circular saw L upon the extreme end of it. This mandrel and its frame being exactly similar to those at G and H, *fig.* 193, do not require a separate view, although they are hidden behind the saw, except the end of the screw, marked A. This frame is screwed down upon the frame B B of the machine, which is supported upon four columns. C C, D D, is an inclined bench, or a kind of trough, in which a block is laid, as at E, being supported on its edge by the plane C C of this bench, and its end kept up to its position by the other part of the bench D D.

By sliding the block along this bench, it is applied to the saw, which cuts off its angles, as is evident from the figure, and prepares it for the shaping engine. All the

Digitized by Google

four angles are cut off in succession, by applying its different sides to the trough or bench. In the figure, two of them are drawn as being cut, and the third is just marked by the saw. This machine is readily adapted to different sizes of blocks, by the simple expedient of laying pieces of wood of different thickness against the plane D D, so as to fill it up, and keep the block nearer to or farther from the saw; for all the blocks are required to be cut at the same angle, though, of course, a larger piece is to be cut from large than from small blocks. The block reduced to the state of E is now taken to.



7. *The shaping machine.* — A great deal of the apparent complication of this figure arises from the iron cage which is provided to defend the workmen, lest the blocks, which are revolving in the circles or chuck with an immense velocity, should be loosened by the action of the tool, and fly out by their centrifugal force. Without this provision, the consequences of such an accident would be dreadful, as the blocks would be projected in all directions, with an inconceivable force.

8. *The scoring engine* receives two blocks as they come from the shaping engine, and forms the groove round the longest diameters for the reception of their ropes or straps, as represented in the two snatch blocks and double block, under *figs.* 193, 194.

A, B, *fig.* 195, represent the above two blocks, each held between two small pillars *a* (the other pillar is hid behind the block), fixed in a strong plate D, and pressed against the pillars by a screw *b*, which acts on a clamp *d*. Over the blocks a pair of circular planes or cutters, E E, are situated, both being fixed on the same spindle, which is turned by a pulley in the middle of it. The spindle is fitted in a frame F F, moving in centres at *e e*, so as to rise and fall when moved by a handle *f*. This brings the cutters down upon the blocks; and the depth to which they can cut is regulated by a curved shape *g*, fixed by screws upon the plate D, between the blocks. Upon this rests a curved piece of metal *h*, fixed to the frame F, and inclosing, but not touching, the pulley. To admit the cutters to traverse the whole length of the blocks, the plate D (or rather a frame beneath it) is sustained between the points of two centres. Screws are seen at *l*, on these centres. The frame inclines when the handle L is depressed. At M is a lever, with a weight at the end of it, counterbalancing the weight of the blocks, and plate D, all which are above the centre on which they move. The frame F is also provided with a counterpoise to balance the cutters, &c. The cutters E E are circular wheels of brass, with round edges. Each has two notches in its circumference, at opposite sides; and in these notches chisels are fixed by screws, to project beyond the rim of the wheel, in the manner of a plane iron before its face.

This machine is used as follows: — In order to fix the block, it is pressed between the two pins (only one of which, at *a*, can be seen in this view), and the clamp *d*, screwed up against it, so as just to hold the block, but no more. The clamp has two claws, as is seen in the figure, each furnished with a ring entering the double prints previously made in the end of the block. These rings are partly cut away, leaving only such a segment of each as will just retain the block, and the metal between them is taken out to admit the cutter to operate between them, or nearly so. In putting the blocks into this machine, the workman applies the double prints to the ends of the claws of the clamps, but takes care that the blocks are higher between the pins *a* than they should be; he then takes the handle *f*, and by it presses the cutters E E (which we suppose are standing still) down upon the blocks, depressing them between their pins at the same time, till the descent of the cutters is stopped by the piece *h* resting on the shape *g*. He now turns the screws *b b*, to fix the blocks tight. The cutters being put in motion cut the scores, which will be plainly seen by the mode of adjustment just described, to be of no depth at the pin-hole; but by depressing the handle L, so as to incline the blocks, and keeping the cutters down upon their shape *g*, by the

Digitized by Google

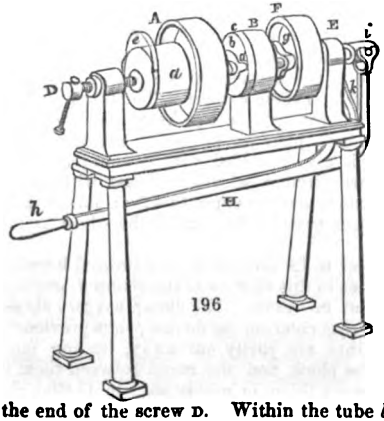
handle *f*, they will cut any depth towards the ends of the blocks, which the shape *g* admits.

By this means one quarter of the score is formed; the other is done by turning both blocks together half round in this manner. The centres *l* are not fitted into the plate D itself, but into a frame seen at R beneath the plate, which is connected with it by a centre pin, exactly midway between the two blocks A B. A spring catch, the end of which is seen at *r*, confines them together; when this catch is pressed back, the plate D can be turned about upon its centre pin, so as to change the blocks, end for end, and bring the unscored quarters (*i. e.* over the clamps) beneath the cutters; the workman taking the handles *f* and L, one in each hand, and, pressing them down, cuts out the second quarter. This might have been effected by simply lifting up the handle L; but in that case the cutter would have struck against the grain of the wood so as to cut rather roughly; but by this ingenious device of reversing the blocks, it always cuts clean and smooth, in the direction of the grain. The third and fourth quarters of the score are cut by turning the other sides of the blocks upwards, and repeating the above operation. The shape *g* can be removed, and another put in its place, for different sizes and curves of blocks; but the pins *a* and holding clamps *d* will suit many different sizes.

By these machines the shells of the blocks are completely formed, and they are next polished and finished by hand labour; but as this is performed by tools and methods which are well known, it is needless to enter into any explanation: the finishing required being only a smoothing of the surfaces. The machines cut so perfectly true as to require no wood to be removed in the finishing; but as they cut without regard to the irregularity of the grain, knots, &c., it happens that many parts are not so smooth as might be wished, and for this purpose manual labour alone can be employed.

The lignum vitæ for the sheaves of the blocks is cut across the grain of the wood by two cross-cutting saws, a circular and straight saw, as before mentioned. These machines do not essentially differ in their principle from the great cross-cutting saws we have described, except that the wood revolves while cutting, so that a small saw will reach the centre of a large tree, and at the same time cut it truly flat. These machines cut off their plates from the end of a tree which are exactly the thickness for the intended sheave. These pieces are of an irregular figure, and must be rounded and centred in the crown saw.

9. *The crown saw* is represented in *fig.* 196, where A is a pulley revolving by means of an endless strap. It has the crown or trepan saw *a* fixed to it, by a screw cut within the piece, upon which the saw is fixed, and which gives the ring or hook of the saw sufficient stability to perform its office. Both the pulleys and saw revolve together upon a truly cylindrical tube *b*, which is stationary, being attached by a flanch *c* to a fixed puppet B, and on this tube as an axis the saw and pulley turn, and may be slid endwise by a collar fitted round the centre piece of the pulley, and having two iron rods (only one of which can be seen at *d* in the figure), passing through holes made through the flanch and puppet B. When the saw is drawn back upon its central tube, the end of the latter projects beyond the teeth of the saw. It is by means of this fixed ring or tube within the saw, that the piece of wood *e* is supported together during the operation of sawing, being pressed forcibly against it by a screw D, acting through a puppet fixed to the frame of the machine. At the end of this screw is a cup or basin which applies itself to the piece of wood, so as to form a kind of vice, one side being the end of the fixed tube, the other the cup the end of the screw D. Within the tube *b* is a collar for supporting a central axis, which is perfectly cylindrical. The other end of this axis (seen at *f*) turns in a collar of the fixed puppet E. The central axis has a pulley F, fixed on it, and giving it motion by a strap similar to the other. Close to the latter pulley, a collar *g* is fitted on the centre piece of the pulley, so as to slip round freely, but at the same time confined to move endwise with the pulley and its collar. This collar receives the ends of the two iron rods *d*. The opposite ends of these rods are, as above mentioned, connected by a similar collar, with the pulley A of the saw *a*. By this connection, both the centre bit, which is screwed into the end of the central axis *f*, and the saw



196

Digitized by Google

sliding upon the fixed tube *b*, are brought forward to the wood at the same time, both being in rapid motion by their respective pulleys.

10. *The coaking engine.*—This ingenious piece of machinery is used to cut the three semi-circular holes which surround the hole bored by the crown saw, so as to produce a cavity in the centre of the disc.

11. *Face-turning lathe.*—The sheave is fixed against a flat chuck, similar to that in the coaking engine, except that the centre pin instead of having a nut is tapped into the flat chuck, and turned by a screwdriver.

A complete set of this block machinery has since been made, by Messrs. Maudslay and Field, for the Spanish Government, from the original drawings and models.

Iron blocks and sheaves have been introduced with great advantage by Messrs. Brown and Lenox, and are used extensively in the naval and merchant services. See IRON.

BLOCK TIN. Metallic tin cast into a block, the weight of which is now about 3½ cwts. Formerly, when it was the custom to carry the blocks of tin on the backs of mules, the block was regulated by what was then considered to be a load for the mule, at 2½ cwts. Subsequently, the block of tin was increased in size, and made as much as two men could lift, or 3 cwts. It was the custom to order so many blocks of tin, and the smelter, being desirous of selling as much tin as possible, continued to increase the size of the block, so that, although 3½ cwts. is the usual weight, many blocks are sold weighing 3¾ cwts. See TIN.

BLOND METAL. A Clayband ironstone found at Wednesbury, is used when smelted, for making tools.

BLOOD. (*Sang*, Fr.; *Blut*, Germ.) The liquid which circulates in the arteries and veins of animals; bright red in the former and purple in the latter, among all the tribes whose temperature is considerably higher than that of the atmosphere. It consists — 1, of a colourless transparent solution of several substances in water; and, 2, of red undissolved particles diffused through that solution. Its specific gravity varies with the nature and health of the animal, being from 1·0527 to 1·0570 at 60° F. It has a saline sub-nauseous taste, and a smell peculiar to each animal. When fresh drawn from the vessels, it rapidly coagulates into a gelatinous mass, called the clot, cruor, or crassamentum, from which, after some time, a pale-yellow fluid, passing into yellowish-green, oozes forth, called the *serum*. If the warm blood be switched with a bundle of twigs as it flows from the veins, the fibrine concretes and forms long fibres and knots, while it retains its usual appearance in other respects. The clot contains fibrine and colouring matter in various proportions. Berzelius found, in 100 parts of the dried clot of blood, 35 parts of fibrine, 58 of colouring matter, 1·3 of carbonate of soda, 4 of an animal matter soluble in water, along with some salts and fat. The specific gravity of the serum varies from 1·027 to 1·029. It forms about three-fourths of the weight of the blood, has an alkaline reaction, coagulates at 157° F. into a gelatinous mass, and has for its leading constituent *albumen* to the amount of 8 per cent. besides fat, potash, soda, and salts of these bases. Blood does not seem to contain any gelatine. The coloured blood corpuscules contain an albuminous substance, the nature of which has not been very satisfactorily made out. Chemists have called the crystalline substance of the red corpuscules of the blood *Hæmato-crystallin*. According to Lehmann, they consist of carbon, 55·41; hydrogen, 7·08; nitrogen, 17·27; sulphur, 0·25; oxygen, 19·99.

Hæmatin is peculiar to the blood corpuscules of vertebrate animals—and a substance called *Hæmatoidin*, has been observed in the blood extravasated in the tissues of living animals. Fat and sugar are found in blood, the quantities varying with the health of the animal. For a very full account of the researches made by chemists on blood. — *Watts' Chemical Dictionary.*

The red colouring matter called *hematosine* may be obtained from the cruor by washing with cold water and filtering. Professor Stokes, in a paper "*On the Reduction and Oxidation of the Colouring Matter of the Blood*," has published some very curious results. By spectrum analysis he has been led to infer that the colouring matter of blood, like indigo, is capable of existing in two states of oxidation, distinguishable by a difference of colour and a fundamental difference in the action on the spectrum. It may be made to pass from the more to the less oxidised state, by the action of suitable reducing agents, and recovers its oxygen by absorption from the air. This colouring matter in its two states of oxidation, Professor Stokes proposes to call *scarlet cruorine* and *purple cruorine*.—*Proceedings of the Royal Society*, vol. xiii. p. 355 (1864).

Mr. Sorby has also published in the "*Quarterly Journal of Science*," No. VI., April 1865, a paper "*On the Detection of Blood Stains by Spectrum Analysis*," in which he shows how it may be employed with great reliance in cases of the highest judicial importance. These two papers should be consulted.

Digitized by Google

Blood may be dried by evaporation at a heat of 130° to 140°, and in this state has been transported to the colonies for purifying cane juice. It is used for making animal charcoal in the Prussian-blue works, and, by an after-process, a decolouring carbon. It is employed in some Turkey-red dye works. Blood is a powerful manure.

Mr. Pillans, in 1854, took out a patent for the separation of the colouring matter of the blood, by which he obtained readily—1st, the clot, in a comparatively dry state, comprising hematosine, with a portion of serum and all the fibrine; 2nd, a portion of serum, highly coloured with hematosine; 3rd, the clear serum.

The blood, in small fragments, is dried on wirework or trays, at a less temperature than will coagulate the hematosine, so that, when dry, it may be soluble in water; 110° to 115° is the temperature recommended.

The clear serum is dried and ground and in a fit state to be used as albumen, and may be employed by the printers of textile fabrics for fixing ultramarine blue and other colours, or as a substitute for egg albumen, both in printing colours and in refining liquids.

BLOODSTONE. A very hard, compact variety of hæmatite iron ore, which, when reduced to a suitable form, fixed into a handle, and well polished, forms the best description of burnisher for producing a high lustre on gilt coat-buttons. The gold on china is burnished by the same means.—*Knight.*

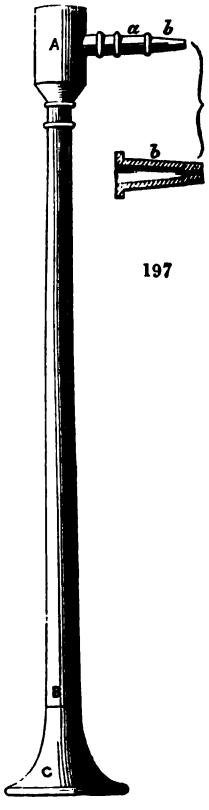
Bloodstone is a name also applied to the jaspery variety of quartz known as the *heliotrope*, coloured deep-green, with interspersed blood-red spots like drops of blood. —*Dana.*

BLOOM. The name given to a mass of iron after it leaves the pudding furnace. See IRON.

BLOOMARY. The old iron furnaces were so called.

BLOWING MACHINE and FANS. See IRON, METALLURGY, VENTILATION.

BLOWPIPE. (*Chalumeau*, Fr.; *Löthrohr*, Germ.) Jewellers, mineralogists, chemists, enamellers, &c., make frequent use of a tube,—usually bent near the end,—terminated with a finely pointed nozzle, for blowing through the flame of a lamp, candle, or gas jet, and producing thereby a small conical flame possessing a very intense heat.



197

The blowpipe is so extremely useful to the manufacturer and to the miner that a more exact description of the instrument is required.

When we propel a flame by means of a current of air blown *into* or upon it, the flame thus produced may be divided into two parts, as possessing different properties—that of *reducing* under one condition and of *oxidising* under another.

The *reducing flame* is produced by blowing the ordinary flame of a lamp or candle simply aside by a weak current of air impinging on its outer surface; it is therefore unchanged except in its direction. Unconsumed carbon, at a white heat, giving the yellow colour to the flame, coming in contact with the substance aids in its reduction.

The *oxidising flame* is formed by pouring a strong blast of air into the *interior* of the flame; combustion is thus thoroughly established, and if a small fragment of an oxidisable body is held just beyond the point of the flame, it becomes intensely heated, and, being exposed freely to the action of the surrounding air, it is rapidly oxidised.

The best form of blowpipe is the annexed (*fig.* 197), which, with the description, is copied from Blandford's excellent translation of Dr. Theodore Scheerer's "Introduction to the Use of the Mouth Blowpipe."

The tube and nozzle of the instrument are usually made of German silver, or silver with a platinum point, and a trumpet-shaped mouth-piece of horn or ivory. Many blowpipes have no mouth-pieces of this form, but are simply tipped with ivory, or some similar material. The air-chamber A serves in some degree to regulate the blast and receives the stem, B, and the nozzle, *a*, which are made separately, and accurately ground into it, so that they may be put together or taken apart at pleasure. The point *b* is best made of platinum, to allow of its being readily cleaned, and is of the form shown in the woodcut. When the instrument is used, the mouth-

Digitized by Google

piece is pressed against the lips, or, if this is wanting, the end of the stem must be held between the lips of the operator. The former mode is far less wearying than the latter; and whereas, with the trumpet mouth-piece, it is easy to maintain a continued blast for five or ten minutes, without it it is almost impossible to sustain an unbroken blast of more than two or three minutes' duration. While blowing, the operator breathes through his nostrils only, and, using the epiglottis as a valve, forces the air through the blowpipe by means of the cheek muscles.

Some years since, Mr. John Prideaux, of Plymouth, printed some valuable "Suggestions" for the use of the blowpipe by working miners. Some portions of this paper appear so useful, especially under circumstances which may preclude the use of superior instruments, &c., that it is thought advisable to transfer them to these pages.

For ordinary metallurgic assays, the common blowpipe does very well. A mere tapering tube, 10 inches long, ¼ inch diameter at one end, and the opening at the other scarcely equal to admit a pin of the smallest kind, the smaller end curved off for 1½ inch to a right angle. A bulb at the bend, to contain the vapour condensed from the breath, is useful in long operations, but may generally be dispensed with. In selecting the blowpipe, the small aperture should be chosen perfectly round and smooth, otherwise it will not command a good flame.

A common candle, such as the miner employs under ground, answers very well for the flame.

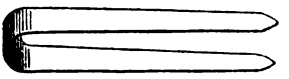
To support the subject of assay, or "the assay," as it has been happily denominated by Mr. Children, two different materials are requisite, according as we wish to calcine or reduce it. For the latter purpose, nothing is so good as charcoal; but that from oak is less eligible, both from its inferior combustibility and from its containing iron, than that from alder, willow, or other light woods.

For calcination, a very convenient support, where platinum wire is difficult to procure, is white-baked pipeclay or china clay, selecting such as will not fuse nor become coloured by roasting with borax.

These supports are conveniently formed by a process of Mr. Tennant. The clay is to be beaten to a smooth stiff body; then a thin cake of it, being placed between a fold of writing paper, it is to be beaten out with a mallet to the thickness of a wafer, and cut, paper and all, into squares of ⅜ths inch diameter, or triangles about the same size. These are to be put in the bowl of a tobacco-pipe, and heated gently till dry, then baked till the paper is burnt away, and the clay left perfectly white. They should be baked in a clear fire, to keep out coal dust and smoke as much as possible, as either of these adhering to the clay plates would colour the borax in roasting. A small fragment of the bowl of a new tobacco-pipe will serve instead in the absence of a more convenient material.

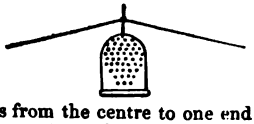
A simple pair of forceps (*fig.* 198). to move and to take up the hot assay, may be made of a slip of stiff tinplate, 8 inches long, ½ inch wide in the middle, and $\frac{1}{16}$th inch at the ends. The tin being rubbed off the points on a rough whetstone, the slip is to be bent until they approach each other within ¼ an inch and the two sides are parallel; thus there will be spring enough in the forceps to open and let go the assay when not compressed upon it by the finger and thumb.

198



A magnetic needle, very desirable to ascertain the presence of iron, is easily made of the requisite delicacy where a magnet is accessible. A bit of thin steel wire, or a long fine stocking-needle, having ¼ inch cut off at the point, is to be heated in the middle that it may be slightly bent there (*fig* 199). While hot, a bit of sealing wax is to be attached to the centre, and the point which had been cut off, being heated at the thick end, is to be fixed in the sealing wax, so that the sharp end may serve as a pivot, descending about ⅛th inch below the centre, taking care that the ends of the needle fall enough below the pivot, to prevent it overturning. It must be magnetised, by sliding one end of a magnet half a dozen or more times from the centre to one end of the needle, and the other end a similar number of times from the centre of the needle to its other end. A small brass thimble (not capped with iron) will do for for the support, the point of the pivot being placed in one of the indentations near the centre of the tap, when, if well balanced, it will turn until it settles north and south. If one side preponderate, it must be nipped until the balance be restored.

199



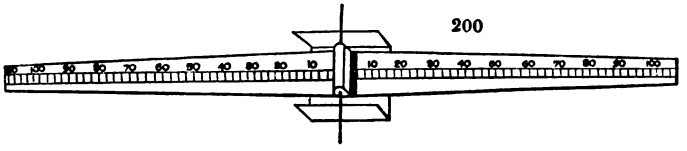
A black gun-flint is also occasionally used to rub the metallic globules (first attached, whilst warm, to a bit of sealing wax), and ascertain the colour of the streak which they give. Thus minute particles of gold, copper, silver, &c., are readily discriminated. A little refined borax and carbonate of soda, both in powder, will complete the requisites.

Digitized by Google

Having collected these materials, the next object for the operator is to acquire the faculty of keeping up an unintermitted blast through the pipe whilst breathing freely through the nose.

A very sensitive and, for most purposes, sufficiently delicate balance (*fig.* 200) was also devised by Mr. Prideaux, of which the following is a description:—

200



The common marsh reed, growing generally in damp places throughout the kingdom, will yield straight joints, from 8 to 12, or more, inches long; an 8-inch joint will serve, but the longer the better. This joint is to be split down its whole length, so as to form a trough, say ¼ inch wide in the middle, narrowed away to ⅓rd inch at the ends. A narrow slip of writing paper, the thinner the better (bank post is very convenient for the purpose), and as long as the reed trough, is to be stuck with common paste on the face of a carpenter's rule, or, in preference, that of an exciseman,—as the inches are divided into tenths instead of eighths;—in either case observing that the divisions of the inch on the rule be left uncovered by the paper. When it is dry, lines must be drawn the whole length of it, ⅛th inch apart, to mark out a stripe ⅛th inch wide. Upon this stripe the divisions of the inch are to be ruled off by means of a small square.

The centre division being marked 0, it is to be numbered at every fourth line to the ends. Thus the fourth from the centre on each side will be 10; the eighth, 20; the twelfth, 30; the sixteenth, 40, &c.; and a slip of 10 inches long, graduated into tenths of an inch, will have on each arm 50 lines, or 125 degrees, divided by these lines into quarters. While the lines and numbers are drying, *the exact centre* of the reed-trough may be ascertained, and marked *right* across, by spots on the two edges. A line of gum water, full ⅛th inch wide, is then laid with a camel-hair pencil along the hollow, and the paper being stripped from the rule (which it leaves easily), the graduated stripe is cut out with scissors, and laid in the trough, with the line 0 exactly in the centre. Being pressed to the gummed reed, by passing the round end of a quill along it, it graduates the trough from the centre to each end. This graduation is very true, if well managed, as the paper does not stretch with the gum water after being laid on the rule with the paste.

A very fine needle is next to be procured (those called *bead*-needles are the finest) and passed through a slip of cork the width of the centre of the trough, about ⅛th inch square, ⅛th thick. It should be passed through with care, so as to be quite straight. The cork should then be cut until one end of it fits into the trough, so that the needle shall bear on the edges exactly in the spots that mark the centre, as it is of importance that the needle and the trough be exactly at right angles with each other. The cork is now to be fixed in its place with gum water, and, when fast dry, to be soldered down on each side with a small portion of any soft resinous cement, on the point of a wire or knitting needle; a little cement being also applied in the same manner to the edges of the cork where the needle goes through, to give it firmness, the beam is finished. It may be balanced by paring the edges on the heaviest side: but accurate adjustment is needless, as it is subject to vary with the dampness or the dryness of the air.

The support on which it plays is a bit of tin plate (or, in preference, brass plate), 1⅛ths inch long, and 1 inch wide. The two ends are turned up square ⅛ths of an inch, giving a base of ⅛ths of an inch wide, and two upright sides ⅛ths high. The upper edges are then rubbed down smooth and square upon a Turkey stone, letting both edges bear on the stone together that they may exactly correspond. For use, the beam is placed evenly in the support, with the needle resting across the edges. Being brought to an exact balance by a bit of writing paper, or any other substance, placed on the lighter side, and moved toward the end until the equilibrium is produced, it will turn with extreme delicacy, a bit of horsehair, ⅛th inch long being sufficient to bring it down freely.

It must not be supposed that any such instrument as this is recommended as in any way substituting the beautiful balances which are constructed for the chemist, and others requiring to weigh with great accuracy. The object is merely to show the miner a method by which he may construct for himself a balance which shall be sufficiently accurate for such blowpipe investigations as it may be important for him to learn to perform for himself. If the suggestions of the chemist who devised the above balance had been carried out, much valuable mineral matter which has been lost might have been turned to profitable account.

Digitized by Google

The blowpipe is largely used in manufactures, as in soldering, in hardening and tempering small tools, in glass-blowing, and in enamelling. In many cases the blowpipes are used in the mouth, but frequently they are supplied with air from a bellows moved by the foot, by vessels in which air is condensed, or by means of pneumatic apparatus.

Many blowpipes have been invented for the employment of oxygen and hydrogen, by the combustion of which the most intense heat which we can produce is obtained. Professor Hare, of Philadelphia, was the first to employ this kind of blowpipe, when he was speedily followed by Clark, Gurney, Leeson, and others. The blowpipe, fed with hydrogen, is employed in many soldering processes with much advantage.

The general form of the "workshop blowpipe" is that of a tube open at one end, and supported on trunnions in a wooden pedestal, so that it may be pointed vertically, horizontally, or at any angle as desired. Common street gas is supplied through one hollow trunnion, and it escapes through an annular opening, while common air is admitted through the other trunnion, which is also hollow, and is discharged in the centre of the hydrogen through a central conical tube; the magnitude and intensity of the flame being determined by the relative quantities of gas and air, and by the greater or less protrusion of the inner cone, by which the annular space for the hydrogen is contracted in any required degree. See AUTOGENOUS SOLDERING.

BLUBBER. The cellular membrane of the whale, containing the oil. See OIL.

BLUE COPPERAS, or BLUE STONE. The commercial or common names of the sulphate of copper. See COPPER.

BLUE JOHN. A beautiful variety of fluor spar, found at Tray Cliff, near Castleton, Derbyshire, from which vases and other ornamental articles are wrought. See FLUOR SPAR.

BLUE LEAD. A name used sometimes by the miners to distinguish galena from carbonate, or white lead. A variety of galena, to which this name has been applied, and which is pseudomorphous after pyromorphite, has been found at Herodsfoot mine, and Huel Hope in Cornwall, and at some mines in Saxony and France. The specimens from Huel Hope would burn in the flame of a candle like the supersulphide of lead.

BLUE PIGMENTS. The blues of vegetable origin, in common use, are indigo and litmus. The blue pigments of a metallic nature found in commerce are the following:— *Prussian blue*; sesqui-ferrocyanide of iron, called also *Berlin blue*; *mountain blue*, a carbonate of copper mixed with more or less earthy matter; *Bremen blue*, or *verditer*, a greenish-blue colour obtained from copper mixed with chalk or lime; *iron blue*, phosphate of iron, but little employed; *cobalt blue*, a colour obtained by calcining a salt of cobalt with alumina or oxide of tin; *smalt*, a glass coloured with cobalt and ground.

Molybdenum blue is a combination of this metal and oxide of tin, or phosphate of lime. A blue may also be obtained by putting into molybdic acid (made by digesting sulphuret of molybdenum with nitric acid), some filings of tin, and a little muriatic acid. The tin deoxidises the molybdic acid to a certain degree, and converts it into the molybdous, which, when evaporated and heated with alumina recently precipitated, forms this blue pigment.

Ultramarine is a beautiful blue pigment.

Turnbull's and *Chinese blues* are both double cyanides of iron.

King's blue.—A carbonate of cobalt.

Saxon blue.—A solution of indigo in sulphuric acid. See these COLOURS.

BLUE VITRIOL. Sulphate of copper. When found in nature, it is due entirely to the decomposition of the sulphides of copper, especially of the yellow copper pyrites, which are liable to this change when placed under the influence of moist air, or of water containing air. See COPPER.

BOGHEAD COAL, *and other Brown Scotch Cannel Coals.* The brown cannels are chiefly confined to Scotland, and have been wrought, with the exception of the celebrated Boghead, for the last thirty years. They are found at Boghead, near Bathgate; Rocksoles, near Airdrie; Pirnie, or Methill; Capeldrea, Kirkness, and Wemyss, in Fife. The first named coal, about which there has been so much dispute as to its nature, has only been in the market eight years. It is considered the most valuable coal hitherto discovered for gas- and oil-making purposes; but, strange to say, the middle portion of the Pirnie, or Methill, seam, which has been unnoticed for thirty years, is nearly as valuable for both purposes.

BOGHEAD. Amorphous; fracture subconchoidal, compact, containing impressions of the stems of *Sigillaria*, and its roots (*Stigmariæ*), with rootlets traversing the mass. Colour, clove-brown, streak yellow, without lustre; a non-electric; takes fire easily, splits, but does not fuse, and burns with an empyreumatic odour, giving out much smoke, and leaving a considerable amount of white ash. H 25. Specific gravity, 1·200.

Digitized by Google

According to Dr. Stenhouse, F.R.S., its composition is:—

Carbon	65·72
Hydrogen	9·03
Nitrogen	0·72
Oxygen	4·78
Ash	19·75
	100·00

Dr. Stenhouse's analysis of the ash of Boghead coal, from three analyses, was as follows:—

Silica	58·31
Alumina	33·65
Sesquioxide of iron	7·00
Potash	0·84
Soda	0·41
Lime and sulphuric acid	traces.

Dr. Andrew Fyfe, F.R.S.E., on analysis, found that the coal yielded, from a picked specimen, 70 per cent. of volatile matter, and 30 per cent. of coke and ash. From a ton he obtained 14·880 cubic feet of gas, the illuminating power of which was determined by the use of the Bunsen photometer, the gas being consumed by argands burning from 2½ to 3¼ feet per hour, according to circumstances. The candle referred to was a spermaceti candle, burning 140 grains per hour.

Cubic Feet of Gas per Ton of Coal.	Specific Gravity.	Condensation by Chlorine in 100 Parts.	Durability 1 foot burns.	Illuminating Power 1 foot = Light of Candles.	Pounds of Coke per Ton of Coal.
14·880	·802	27	Min. Sec. 88 25	7·72	760

The Pirnie or Methill brown cannel, on analysis, gives the following results:—

Specific gravity	1·126
Gas per ton	13,500 feet
Illuminating power	28 candles
Coke and ash	36 per cent.
Hydro-carbons condensed by bromine	20 ,,
Sulphuretted hydrogen	½ ,,
Carbonic acid	4½ ,,
Carbonic oxide	7¾ ,,
Volatile matter in coal	65 ,,
Specific gravity of gas	·700

The Boghead coal occurs in the higher part of the Scotch coal field; in about the position of the "slaty band" of ironstone, its range is not more than 3 or 4 miles in the lands of Torbane, Inchcross, Boghead, Capper's, and Bathvale, near Bathgate, in the county of Linlithgow. In thickness it varies from 1 to 30 inches, and at the present consumption, say from 80,000 to 100,000 tons per annum, it cannot last many years.

The following section of a pit at Torbane shows that the cannel occurs in ordinary coal measures, and under circumstances common to beds of coal:—

	Ft.	In.
Boghead house coal	2	7
Arenaceous shale	6	0
Slaty sandstone	0	7
Shale and ironstone, containing remains of plants and shells	0	10
Cement stone (impure ironstone)	0	4
Boghead cannel	1	9
Fire clay, full of *Stigmariæ*	0	5
Coal (common)	0	6
Black shale	0	0¾
Coal	0	1
Shale	0	0⅜
Coal	0	0½
Fire clay	0	1½
Hard shale	0	3
Thin laminæ of coal and shale	0	3½
Common coal	0	6
Fire clay	0	0

Digitized by Google

One of the chief characters of this cannel is its indestructibility under atmospheric agencies; for whether it is taken from the mine at a depth of fifty fathoms, or at the outcrop, its gas- and oil-yielding properties are the same. Even a piece of the mineral taken out of the drift deposits, where it had most probably lain for thousands of years, appears to be just the same in quality as if it had been but lately raised from the mine.

In the earth the seam lies parallel to its roof and floor, like other beds of coal; and it is traversed by the usual vertical joints, dividing it into the irregular cubes which so generally characterise beds of cannel. The roof lying above the cement stone contains remains of *Calamites;* and the ironstone nodules, fossil shells of the genus *Unio.* The floor of the mine contains *Stigmariæ;* and the coal itself affords more upright stems of *Sigillariæ*, and its roots (*Stigmariæ*) and their radicles, running through the seam to a considerable distance, than the majority of coals show. In these respects it entirely resembles the Pirnie or Methill seam. Most cannels afford remains of fish; but in Boghead no traces of these fossils have yet been met with, although they have been diligently sought after.

The roots in the floors, and the upright stems of trees in the seam itself, appear to show that the vegetable matter now forming the coal grew on the spot where it is found. If the mangroves and other aquatic plants, at the present day found growing in the black vegetable mud of the marine swamps of Brass town, on the west coast of Africa, were quietly submerged and covered up with clay and silt, we should have a good illustration of the formation of a bed of carbonaceous matter showing no structure, mingled with stems and roots of trees showing structure, which is the case of Boghead coal, the structure being only detected in those parts showing evidence of stems and roots, and not in the matrix in which those fossils are contained.

The chemical changes by which vegetable matter has been converted into Boghead cannel will not be here dwelt on; but the chief peculiarity about the seam is its close and compact roof, composed of cement-stone, and shale. This is perfectly water and air tight, so much so that, although the mine is troubled with a great quantity of water, it all comes through the floor, and not the roof. This tight covering of the coal has doubtless exercised considerable influence on the decomposing vegetable matter after the latter had been submerged. It is worthy of remark that, above the Pirnie or Methill seam,—the coal nearest approaching Boghead,—a similar bed of impure ironstone occurs.

Away from whin dykes which traverse the coal field, there are no appearances of the action of an elevated temperature, either upon the coal or its adjoining strata, to give any sanction to the hypothesis, that the cannel has resulted from the partial decomposition of a substratum of coal by the heat of underlying trap, the volatile matters having been retained in what has probably been a bed of shale. First, it must be understood that Boghead cannel, even when treated with boiling naphtha, affords scarcely a trace of bitumen; and, secondly, when the seam of coal is examined in the neighbourhood of a whin dyke, where heat has evidently acted on it, it is found nothing like cannel, but as a soft sticky substance, of a brown colour, resembling burnt Indian-rubber. Besides these facts, the seams of coal and their accompanying strata, both above and below the cannel, show no signs of the action of heat, but, on the contrary, exhibit every appearance of having been deposited in the usual way, and of remaining without undergoing any particular alteration.—E. W. B. See CANNEL COAL.

BOG. (Celtic, *soft.*) See PEAT.

BOG BUTTER. A fatty spermaceti-like substance found in the peat mosses. See ADIPOCERE.

BOGHEAD NAPHTHA (*syn.* Bathgate naphtha), naphtha from the Boghead coal. See NAPHTHA, BOGHEAD.

BOG IRON ORE is an example of the recent formation of an ore of iron, arising from the decomposition of rocks containing iron, by the action of water charged with carbonic acid. The production of this ore of iron in the present epoch, explains to us many of the conditions under which some of the more ancient beds of iron ore have been produced.

Bog-iron ore is common in the peat bogs of Ireland and other places. See IRON ORES and IRON.

BOG MANGANESE. *Wad*, or earthy manganese. See MANGANESE.

BOG WOOD. The trunks and larger branches of trees dug up from peat bogs. The black oak of the bogs of Ireland, which is so largely employed in the manufacture of ornaments, is so called.

BOHEA. A kind of black tea. See TEA.

BOHEMIAN BOLE. A yellow variety of bole.

Digitized by Google

BOILED OIL. Linseed oil boiled with litharge, which removes some of oleaginous parts, and renders the oil more "drying," that is, it solidifies more readily.

BOILER. See STEAM BOILER.

BOILER PLATE. Sheets of iron used for making boilers, and now largely employed for constructing railway bridges, ships, tanks, &c. The average resistance of boiler plates is reckoned at 20 tons to the square inch, and the weight which they can carry safely is about 5 tons on the square inch. Rivetting is calculated to reduce the strength to a degree corresponding to that of the area which the rivets occupy. Such are the principles by which the Railway Department of the Board of Trade are guided. See IRON.

BOIS DURCI. Finely powdered sawdust, and turnings of hard wood, such as rosewood, ebony, mahogany, and the like, are made into a paste with blood, which is pressed into moulds or formed by dies. It receives a beautiful polish, equal to jet, which it much resembles. This was first introduced to England in 1862 by M. Latry, senior.

BOLE. A kind of clay, often highly coloured by iron. It usually consists of silica, alumina, iron, lime, and magnesia. It is not a well-defined mineral, and, consequently, many substances are described by mineralogists as bole. *Armenian bole* is of a bright red colour. This is frequently employed as a dentifrice, and in some cases it is administered medicinally. *Bole of Blois* is yellow, contains carbonate of lime, and effervesces with acids. *Bohemian bole* is a yellowish red. *French bole* is of a pale red, with frequent streaks of yellow. *Lemnian bole* and *Silesian bole* are, in most respects, similar to the above-named varieties. The following analyses are by C. Von Hauer. Capo di Bove—Silica, 45·64; alumina, 29·33; peroxide of iron, 8·88; lime, 0·60; magnesia, a trace; water, 14·27 = 98·72. New Holland—Silica, 38·22; alumina, 31·00; peroxide of iron, 11·00; lime, a trace; magnesia, a trace-water, 18·81 = 99·03.

BOLETUS. A genus of mushroom. See AMADOU.

BOLOGNIAN STONE. A sulphate of barytes, found in roundish masses, which phosphoresces when, after calcination, it is exposed to the solar rays.

BOMBASINE. A worsted stuff mixed with silk; it is a twilled fabric of which the warp is silk and the weft worsted.

BOMBYX MORI. The moth to which the silkworm turns. The caterpillar (silkworm) is at first of a dark colour; but gradually, as with all other caterpillars, it becomes lighter coloured. This worm is about eight weeks in arriving at maturity, during which time it frequently changes its colour. When full grown, the silkworm commences spinning its web in some convenient place. The silkworm continues drawing its thread from various points, and attaching it to others; it follows, therefore, that after a time the body becomes, in a great measure, enclosed in the thread. The work is then continued from one thread to another, the silkworm moving its head and spinning in a zigzag way, bending the fore part of the body back to spin in all directions within reach, and shifting the body only to cover with silk the part which was beneath it. As the silkworm spins its web by thus bending the fore part of the body back, and moves the hinder part of the body in such a way only as to enable it to reach the farther back with the fore part, it follows that it encloses itself in a cocoon much shorter than its own body; for soon after the beginning, the whole is continued with the body in a bent position. During the time of spinning the cocoon, the silkworm decreases in length very considerably; and after it is completed it is not half its original length; at this time it becomes quite torpid, soon changes its skin, and appears in the form of a chrysalis. The time required to complete the cocoon is five days. In the chrysalis state the animal remains from a fortnight to three weeks; it then bursts its case, and comes forth in the *imago state*, the moth having previously dissolved a portion of the cocoon by means of a fluid which it ejects.

The late Colonel Sir William Reid reports as follows on the *Bombyx Cynthia*:—

"I made several reports on the *Bombyx Cynthia* silkworm, which feeds on the castor-oil plant, for the information of the Society of Arts. It had been introduced into Malta from India, in that year, and appeared both hardy and wonderfully prolific; yet it failed in Malta in 1855.

"2. I had, however, previously distributed a great number of eggs, by sending them to Italy, France, and Algeria; and I contrived to watch the accounts of the trials made in those countries. I found that it had spread there, and had been carried to Spain and Portugal, and was creating considerable interest wherever it had been tried.

"3. I was, therefore, induced to re-introduce it into Malta. At the end of July last, I received a few eggs by post, in a quill, from Paris; and these have multiplied

Digitized by Google

in an extraordinary manner, so that I have not attempted to have them counted. The temperature of the winter season, now December, seems, however, to be affecting them, even in Malta, inasmuch as they grow more slowly than they did in the summer; but, nevertheless, they appear healthy.

"4. A very interesting paper, on the progress making in different countries in rearing the *Bombyx Cynthia*, will be found in the last number of the papers of the French Société d'Acclimation. This paper is by the able President of that society, M. Geoffroy Saint Hilaire.

"5. I had, in 1854, successfully sent the insect to the West Indies. The French Society have sent it to Brazil, to the Southern United States, and into Egypt. It is being introduced into Germany, and we are now sending more eggs and worms from Malta to Sicily.

"6. Experiments are making in France on spinning the silk, which is found to be very fine, very strong, and to take dyes well. In France the cocoons are corded, and afterwards spun, as in Malta. It is said that the chrysalis, on extricating itself from the cocoon and becoming a moth, does not, as was supposed, cut the thread; and the French have partially succeeded in unwinding the cocoons.

"7. The great interest I find taken in other countries in the attempts making to naturalise the *Bombyx Cynthia*, has induced me to report to you its re-introduction into Malta, with the view of begging you to make this known to the Society of Arts. I inclose an extract from my despatch, dated 7th of July, 1855, which explains the manner in which I successfully sent the insect to the West Indies; and in the same manner it may be easily conveyed from any one country to another. It may be found difficult to preserve the silkworm throughout the winter season, as well as difficult to grow the *Ricinus*, its proper food, in the climate of Europe. The proper climate for the *Bombyx Cynthia* is within, or on the borders of, the tropics. But the attempts now making ought not to be the less encouraged on that account, for they are producing a new raw material for thread and clothing within reach of men of skill and science; and 127,000 cocoons have recently been sent from Algeria to be manufactured in Alsace.

"8. The extraordinary manner in which the *Bombyx Cynthia* multiply, together with the abundance of food for them produced without culture in warm climates, renders the study of the habits of this insect, and the nature of its cocoons, of considerable importance.

"9. I send herewith a small sample of the cloth made from the worms reared in Malta.

"I have the honour to be, Sir,
"Your most obedient humble servant,
"WILLIAM REID, Governor."

Additional information on the *Bombyx Cynthia*, or Eria Silkworm, will be found in the "Society of Arts Journal" of June 4th, 1858.

Mr. Wells, writing from Grenada, in the West Indies, says, of these silkworms forwarded to him by Sir William Reid:—"I have the eighth generation of worms now hatching, having had seven crops of cocoons within the year. These worms multiply one hundredfold in each generation; and there is no doubt of their being easily fed to any amount." They are fed on the castor-oil plant, *Ricinus communis*, which grows rapidly, can be cultivated without much expense, and yields a good return in its very abundant seeds. See SILK.

BON-BONS. Comfits and other sweetmeats of various descriptions pass under this name. A large quantity is regularly imported from France into this country, and, from its usually superior quality, it is much in request. The manufacture of sweetmeats, confectionary, &c., does not enter so far into the plan of this work as to warrant our giving any special detail of the various processes employed; a general notice will however be found under the head of CONFECTIONARY.

Liqueur Bon-bons are made in the following manner. A syrup evaporated to the proper consistence is made, and some alcoholic liqueur is added to it. Plaster of Paris models of the required form are made; and these are employed, several being fastened to a rod, for the purpose of making moulds in powdered starch, filling shallow trays. The syrup is then, by means of a funnel, poured into these moulds, and there being a powerful repulsion between the starch and the alcoholic syrup, the upper portion of the fluid assumes a spherical form; then some starch is sifted over the surface, and the mould is placed in a warm closet. Crystallisation commences on the outside of the bon-bon, forming a crust inclosing the syrup, which constantly gives up sugar to the crystallising crust until it becomes sufficiently firm to admit of being removed. A man and two boys will make three hundredweights of bon-bons in a day.

Crystallised Bon-bons are prepared by putting them with a strong syrup contained

Digitized by Google

in shallow dishes, placed on shelves in the drying chamber, pieces of linen being stretched over the surface, to prevent the formation of a crust upon the surface of the fluid. In two or three days the bon-bons are covered with crystals of sugar; the syrup is then drained off, and the comfits dried.

Painted Bon-bons.—Bon-bons are painted by being first covered with a layer of glazing; they are then painted in body colours, mixed with mucilage and sugar.

The French have some excellent regulations, carried out under the "Préfet de Police," as to the colours which may be employed in confectionary. These are to the following effect:—

"Considering that the colouring matter given to sweets, bon-bons, liqueurs, lozenges, &c., is generally imparted by mineral substances of a poisonous nature, which imprudence has been the cause of serious accidents; and, that the same character of accidents have been produced by chewing or sucking the wrapping paper of such sweets, it being glazed and coloured with substances which are poisonous; it is expressly forbidden to make use of any mineral substance for colouring liqueurs, bon-bons, sugar-plums, lozenges, or any kind of sweetmeats or pastry. No other colouring matter than such as is of a vegetable character shall be employed for such a purpose. It is forbidden to wrap sweetmeats in paper glazed or coloured with mineral substances. It is ordered that all confectioners, grocers, dealers in liqueurs, bon-bons, sweetmeats, lozenges, &c., shall have their name, address, and trade printed upon the paper in which the above articles shall be enclosed. All manufacturers and dealers are personally responsible for the accidents which shall be traced to the liqueurs, bon-bons, and other sweetmeats manufactured or sold by them."

If similar provisions were in force in this country, it would prevent the use, to an alarming extent, in our cheap confectionary, of such poisonous substances as

Arsenite of copper,	Sulphide of arsenic,
Acetate of copper,	Oxide of lead,
Chromate of lead,	Sulphide of mercury, &c.

The colouring matters allowed to be used in France are indigo, Prussian blue, saffron, Turkey yellow, quercitron, cochineal, Brazil wood, madder, &c.

BONES. (*Os*, Fr.; *Knochen*, Gr.) They form the framework of animal bodies, commonly called the skeleton, upon which the soft parts are suspended, or in which they are enclosed. Bones are invested with a membrane styled the periosteum, which is composed of a dense tissue affording glue; whence it is convertible into jelly, by ebullition with water. Bones are not equally compact throughout their whole substance: the long ones have tubes in their centres, lined with a kind of periosteum of more importance to the life of the bones than even their external coat; the flat, as well as the short and thick, bones exhibit upon their surface an osseous mass of a dense nature, while their interior presents a cavity divided into small cellules by their bony partitions.

In reference to the composition of bones. we have to consider two principal constituents; the living portion or the osseous cartilage, and the inorganic or the earthy salts of the bones.

The osseous cartilage is obtained by suspending bones in a large vessel full of dilute muriatic acid, and leaving it in a cool place at about 50° F. The acid dissolves the earthy salts of the bones without perceptibly attacking the cartilage, which, at the end of a short time, becomes soft and translucid, retaining the shape of the bones; whenever the acid is saturated before it has dissolved all the earthy salts. it should be renewed. The cartilage is to be next suspended in cold water, which is to be frequently changed till it has removed all the acidity. By drying, the cartilage shrinks a little, and assumes a darker hue, but without losing its translucency. It becomes, at the same time, hard and susceptible of breaking when bent, but it possesses great strength.

This cartilage is composed entirely of a tissue passing into gelatine. By boiling with water, it is very readily convertible in a glue, which passes clear and colourless through the filter, leaving only a small portion of fibrous matter insoluble by further boiling. This matter is produced by the vessels which penetrate the cartilage, and carry nourishment to the bone. We may observe all these phenomena in a very instructive manner, by macerating a bone in dilute muriatic acid, till it has lost about the half of its salts; then washing it with cold water, next pouring boiling water upon it, leaving the whole in repose for 24 hours, at a temperature a few degrees below 212° F.

The cartilage, which has been stripped of its earthy salts, dissolves, but the small vessels which issue from the undecomposed portion of the bone remain under the form of white plumes, if the water has received no movement capable of crushing or breaking them. We may then easily recognise them with a lens, but the slightest touch tears them. and makes them fall to the bottom of the vessel in the form of a precipitate; if we digest bones with strong hot muriatic acid, so as to accelerate their decomposition, a

Digitized by Google

portion of the cartilage dissolves in the acid with a manifest disengagement of carbonic acid gas, which breaks the interior mass, and causes the half-softened bone to begin to split into fibrous plates, separable in the direction of their length. According to Marx, these plates, when sufficiently thin, possess, like scales of mica, the property of polarising light, a phenomenon which becomes more beautiful still when we soak them with the essential oil of the bark of the Laurus Cassia. The osseous cartilage is formed before the earthy part. The long bones are then solid, and they become hollow only in proportion as the earthy salts appear. In the new-born infant, a large portion of the bones is but partially filled with these salts; their deposition in the cartilage takes place round certain invariable *points of ossification*, and begins at a certain period after conception, so that we may calculate the age of the fœtus according to the progress which ossification has made.

Composition of Bones.

	Heintz.			Berzelius.
	Ox. Femur.	Sheep.	Man. Forearm.	Human Tooth.
Animal matter - - - - -	30·58	26·54	31·11	28·00
Phosphate of lime - - - - -	57·67	61·99	59·14	64·30
Fluoride of calcium - - - -	2·69	2·97	2·23	
Carbonate of lime - - - - -	6·99	6·92	6·32	5·30
Phosphate of magnesia - - - -	2·07	1·58	1·20	1·40

Heintz found that the fixed bases in the bones were sufficient to saturate completely the acids contained in them, so that the phosphate of lime, as well as the phosphate of magnesia, which the bones contain, is composed according to the formula $3RO,PO^5$. Bone phosphate of lime was considered by Berzelius to be $8CaO,3PO^5$. True bony structure is perfectly free from chlorides, from sulphates, and from iron, these salts being only found when the liquid pervading the bones has not been completely removed. The bones in youth contain less earthy constituents than those of adults; and, in advanced age, the proportion of mineral matters increases. Von Biria found more bone earth in the bones of *birds* than in those of mammals; he found also the ratio of the carbonate of lime to the phosphate to be generally greater. In the bones of *amphibia*, he found less inorganic matter than in those of mammals and birds; and, in the bones of *fishes*, the earthy matters vary from 21 to 57 per cent. The scales of fishes have a composition somewhat similar to that of bone, but they contain phosphate of lime in small quantity only.

In certain diseases (the *craniotabes* in children), the earthy salts fall in the spongy portion of the bone as low as 28·16 per cent. of the dry bone; and in several cases the proportion of earthy matter was found by Schlossberger as low as 50 per cent. At the age of 21 years, the weight of the skeleton is to that of the whole body in the ratio of 10·5 : 100 in man, and in that of 8·5 : 100 in woman, the weight of the body being about 125 or 130 lbs.

The quantity of organic matter in *fossil bones* varies very considerably: in some cases it is found in as large a quantity as in fresh bones, while in others it is altogether wanting. Carbonate of lime generally occurs in far larger quantity in fossil than in recent bones, which may arise from infiltration of that salt from without, or from a decomposition of a portion of the phosphate of lime by carbonic acid or carbonates. Magnesia often occurs in larger quantities in the fossil remains of vertebrated animals than in the fresh bones of the present animal world. Liebig found in the cranial bones excavated at Pompeii a larger proportion of fluoride of calcium than in recent bones; while, on the other hand, Girardin and Preisser found that this salt had greatly diminished in bones which had lain long in the earth, and, in some cases, had even wholly disappeared.

The gelatinous tissue of bones was found by Von Biria to consist of:—

	Ox bones.	Fossil bones.
Carbon - - - -	50·401	50·130
Hydrogen - - - -	7·111	7·073
Nitrogen - - - -	18·154	18·449
Oxygen - - - -	24·119	24·348
Sulphur - - - -	0·216	

This is the same composition as that of the gelatinous tissues.

In the arts, bones are employed by turners, cutlers, manufacturers of animal charcoal, and, when calcined, by assayers, for making cupels. In agriculture, they are em-

Digitized by Google

ployed as a manure. Laid on in the form of dust, at the rate of 30 to 35 cwts. per acre, they have been known to increase the value of old pastures from 10*s.* or 15*s.* to 30*s.* or 40*s.* per acre; and after the lapse of 20 years, though sensibly becoming less valuable, land has remained still worth two or three times the rent it paid before the bones were laid on. In the large dyeing establishments in Manchester, the bones are boiled in open pans for 24 hours, the fat skimmed off and sold to the candle makers, and the *size* afterwards boiled down in another vessel till it is of sufficient strength for stiffening the thick goods for which it is intended. The *size* liquor, when exhausted or no longer of sufficient strength, is applied with much benefit as a manure to the adjacent pasture and artificial grass lands, and the exhausted bones are readily bought up by the Lancashire and Cheshire farmers. When burned bones are digested in sulphuric acid diluted with twice its weight of water, a mixture of gypsum and acid phosphate of lime is obtained, which, when largely diluted with water, forms a most valuable liquid manure for grass land and for crops of rising corn; or, to the acid solution, pearl ashes may be added, and the whole then dried up, by the addition of charcoal powder or vegetable mould, till it is sufficiently dry to be scattered with the hand as a top dressing, or buried in the land by means of a drill.

In France, soup is extensively made by dissolving bones in a steam heat of two or three days' continuance. Respecting the nutritive property of such soup, Liebig has expressed the following strong opinion:—"Gelatine, even when accompanied by the savoury constituents of flesh, is not capable of supporting the vital process; on the contrary, it diminishes the nutritive value of food, which it renders insufficient in quantity and inferior in quality, and it overloads the blood with nitrogenous products, the presence of which disturbs and impedes the organic processes." The erroneous notion that gelatine is the active principle of soup arose from the observation that soup made, by boiling, from meat, when concentrated to a certain point, *gelatinises*. The jelly was taken to be the true soup until it was found that the best meats did not yield the finest gelatine tablets, which were obtained most beautiful and transparent from tendons, feet, cartilage, bones, &c. This led to an investigation on nutrition generally, the results of which proved that gelatine, which by itself is tasteless, and when eaten excites nausea, possesses no nutritive value whatever.

The following Table exhibits the relation between the combustible animal matter and the mineral substances of bones, as found by different observers:—

	Organic Portion.	Inorganic Portion.	Observers.
Ox bones	1	2·0	Berzelius.
	1	2·1	Marchand.
Human bones	1	2·0	Berzelius.
	1	1·8 to 2·3	Frerichs.
	1	2·0 in mean	
	1	1·6 to 2·2	Von Biria.
	1	1·9 in mean	
Bird bones	1	2·3 to 2·6	

Prior to the use of bones by the turner or carver, they require the oil, with which they are largely impregnated, to be extracted, by boiling them in, water and bleaching them in the sun or otherwise. This process of boiling, in place of softening, robs them of part of their gelatine, and therefore of part of their elasticity and contractibility likewise, and they become more brittle.

The forms of the bones are altogether unfavourable to their extensive or ornamental employment: most of them are very thin and curved, contain large cellular cavities for marrow, and are interspersed with vessels that are visible after they are worked up into spoons, brushes, and articles of common turnery. The buttock and shin bones of the ox and calf are almost the only kinds used. To whiten the finished works, they are soaked in turpentine for a day, boiled in water for about an hour, and then polished with whitening and water.

Holtzapffel also informs us that after the turning tool, or scraper, has been used, bone is polished, 1st, with glass paper; 2nd, with Trent sand, or Flanders brick, with water on flannel; 3rd, with whiting and water on a woollen rag; 4th, a small quantity of white wax is rubbed on the work with a quick motion; the wax fills the minute pores, but only a very minute portion should be allowed to remain on the work. Common bone articles, such as nail and tooth brushes, are frequently polished with slaked lime used wet on flannel or woollen cloth. See "On Bone and its Uses," by Arthur Aitkin, *Trans. of Society of Arts*, 1832 and 1839.

The importance of the trade in bones will be seen from the following statement of *Imports*, in 1864, of the bones of animals and fish—not whalebone.

BONE BLACK (*Noir d'os*, Fr.; *Knochenschwartz*, Germ.), or *Animal Charcoal*, as it is less correctly called, is the black carbonaceous substance into which bones are converted by calcination in close vessels. This kind of charcoal has two principal applications—to deprive various solutions, particularly syrups, of their colouring matters, and to furnish a black pigment. The latter subject will be treated of under IVORY BLACK.

The discovery of the antiputrescent and decolouring properties of charcoal in general is due to Lowitz, of Petersburg; but their modifications have occupied the attention of many chemists since his time. Kels published, in 1798, some essays on the decolouring of indigo, saffron, madder, syrup, &c., by means of charcoal; but he committed a mistake in supposing bone black to have less power than the charcoal of wood. The first useful application of charcoal to the purification of raw colonial sugar was made by M. Guillon, who brought into the French markets considerable quantities of fine syrups, which he discoloured by ground wood charcoal, and sold them to great advantage, as much superior to the *cassonades* (brown sugars) of that time. In 1811, M. Figuier, an apothecary at Montpellier, published a note about animal charcoal, showing that it blanched vinegars and wines with much more energy than vegetable charcoal; and lastly, in 1812, M. Derosnes proposed to employ animal charcoal in the purification of syrups and sugar refining. The quantities of bone black left in the retorts employed by MM. Payen, for producing crude carbonate of ammonia, furnished abundant materials for making the most satisfactory experiments, and enabled these gentlemen soon to obtain ten per cent. more of refined sugar from the raw article than had been formerly extracted, and to improve, at the time, the characters of the lumps, bastards, treacle, &c.

The calcination of bones is effected by two different systems of apparatus; by heating them in a retort similar to that in which coal is decomposed in the gas works, or in small pots piled up in a kiln. On the second plan, which furnishes the best charcoal, the bones, broken into pieces, are put into small cast-iron pots of the form shown in *fig.* 201, about three-eighths of an inch thick, two of which are dexterously placed with their mouths in contact, and then luted together with loam. The lip of the upper pot is made to slip inside the under one. These double vessels, containing together about fifty pounds of bones, are arranged alongside, and over each other, in an oven like a potter's kiln, till it is filled. The oven or kiln may be either oblong or upright. The latter is represented in *figs.* 202, 203, 204. A is the fire-place or grate for the fuel; C C are the openings in the dome of the furnace through which the flame flows; the divisions of these orifices are shown in *fig.* 204. B is the wall of brick-work. D the space in which the pots are distributed. E is the door by which the workman carries in the pots, which is afterwards built up with fire-

Digitized by Google

bricks, and plastered over with loam. This door is seen in *fig.* 202. F F are the lateral flues for conveying the disengaged gases into the air.

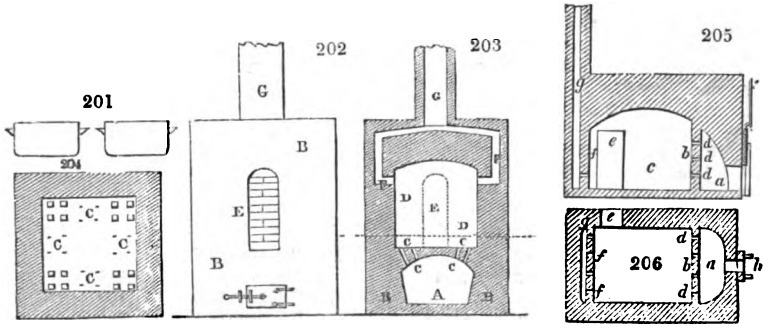

Fig. 205 is a longitudinal section, and *fig.* 206 a ground plan of a horizontal kiln for calcining bones. *a* is the fire-chamber, lying upon a level with the sole of the kiln; it is separated by a pillar *b*, from the calcining hearth *c*. In the pillar or wall, several rows of holes, *d*, are left at different heights; *e* is the entrance door; *f*, the outlet vents for the gases, vapours, and smoke, into the chimney *g*; *h*, a sliding damper-plate for regulating the admission of the air into the fire in the space *a*.

By this arrangement the offensive emanations are partly consumed, and partly carried off with the smoke. To destroy the smell completely, the smoke should be made to pass through a second small furnace.

The number of pots that may be put into a kiln of this kind depends, of course, upon its dimensions; but, in general, from 100 to 150 are piled up over each other, in columns, at once; the greatest heat being nearest the roof of the kiln, which resembles, in many respects, that used for baking pottery ware.

In both kilns the interior walls are built of fire-bricks. In the oblong one, the fiercest heat is near the vaulted roof; in the upright one, near the sole; and the pots, containing the larger lumps of bones, should be placed accordingly near the top of the former and the bottom of the latter. Such a kiln may receive about seventy double pots, containing in the whole thirty-five cwts. of bones.

After the hearth is filled with the pots, and the entrance door is shut, the fire is applied at first moderately, but afterwards it must be raised, and maintained at a brisk heat for eight or ten hours. The door of the ash-pit and the damper may now be nearly closed, to moderate the draught, and to keep up a steady ignition for six or eight hours longer, without additional firing; after which the doors must be all opened to cool the furnace. When this is done, the brick-work of the entrance-door must be taken down, the kiln must be emptied, and immediately filled again with a set of of pots previously filled with bones, and luted together: the pots which have been ignited may, in the course of a short time, be opened, and the contents put into the magazine. But in operating with the large decomposing cylinder retort, the bones being raked out hot, must be instantly tossed into a receiver, which can be covered in air-tight till they are cool.

The bones lose upon an average about one-half of their weight in the calcination. In reference to the quality of the black, experience has shown that it is so much more powerful as a decolouring agent, as the bones from which it was made have been freer from adhering fatty, fleshy, and tendinous matters.

The charcoal is ground in mills with grooved rollers, in order to prevent the formation of dust. The bones are thrown into a long quadrangular box, furnished at its lower aperture with movable steel cheeks, between which the roller revolves; they are thus coarsely broken up, and the granulation is completed by another pair of bluntly grooved rollers, which can be placed nearer to, or further from, each other at pleasure. The crushed charcoal is collected on sieves, which separate the dust from the grains.

The composition of perfectly dry bone black of average quality is as follows:— Phosphate of lime, with carbonate of lime, and a little sulphuret of iron, or oxide of iron, 88 parts; iron in the state of silicated carburet, 2 parts; charcoal containing about $\frac{1}{13}$th of nitrogen, 10 parts. None of the substances present, except the charcoal, possess separately any decolorising power.

It was formerly supposed that the peculiar absorbing and decolouring power of animal charcoal was only exerted towards bodies of *organic* origin; but it was found,

Digitized by Google

by Graham, that *inorganic* substances are equally subject to this action; and later experiments have demonstrated that there are few, if any, chemical compounds which altogether resist the absorbing power of charcoal. The action is of a mechanical nature, and in some cases it is sufficiently powerful to overcome chemical affinities of considerable power. It is not confined to charcoal, though pre-eminent in this substance, in consequence of the immense extent of surface which its porous structure presents. The action of charcoal in sugar refining has been particularly studied by Lüdersdorf. When the defecated saccharine juice is allowed to flow upon a moist and firmly compressed charcoal filter, pure water is the first product that passes through; but a considerably larger quantity is obtained than was employed for moistening the charcoal. Water is then obtained of a decidedly saline character, which increases in strength, and after this has passed through for some time, a sweet taste becomes perceptible, which gradually increases, and at last entirely masks the saline. This purely sweet fluid continues to flow for some time; after which, the liquid acquires an alkaline reaction from the presence of caustic lime; it then becomes coloured, the liquor getting gradually darker, till the action of the charcoal ceases. Lime is completely abstracted from lime water by bone charcoal; and, according to the experiments of Chevallier, lead salts are likewise entirely absorbed, the acetate the most readily. It has also been shown by Graham, that iodine even is separated from iodide of potassium. The commercial value of animal charcoal has usually been estimated by its decolouring power on sulphate of indigo; its absorbent power, which is a property of equal, perhaps of greater importance, may, according to M. Corenwinder, be determined, approximatively, by the quantity of lime which a given weight will absorb. For this purpose he employs a solution of saccharate of lime of known strength. An acid liquor is first prepared, composed of 20 grammes of pure oil of vitriol diluted with water to exactly 1 litre. A solution of saccharate of lime is then prepared, by dissolving 125 to 130 grammes of white sugar in water, adding thereto 15 to 20 grammes of quick-lime, boiling the liquid, and then filtering to separate the undissolved lime. This solution is prepared of such a nature, that it will be exactly saturated by the same volume of the dilute sulphuric acid. By adding the latter to 50 cubic centimetres of the liquid filtered from the animal charcoal, it is easy to see how many degrees of the burette are required to complete the saturation of the lime. Suppose 35 are required for this purpose, $100-35=65$, which represent the proportion of lime absorbed by the charcoal: this is, therefore, the number representing the standard. By operating with a burette graduated from the bottom, the degree of the charcoal experimented upon may be read directly.

This decolourising power does not belong alone to bone black; different varieties of lignite, or even coal, when well carbonised in close vessels, afford a decolouring charcoal of considerable value. By reducing 100 parts of clay into a thin paste with water, kneading into it 20 parts of tar and 500 of finely ground pit-coal, drying the mixed mass, and calcining it out of contact of air, a charcoally matter may be obtained not much inferior to bone black in whitening syrups.

The restoration of animal charcoal from burnt bones, for the purpose of sugar refining, has been long practised in France. Mr. W. Parker has made the following process the subject of a patent. The charcoal, when taken from the vessels in which it has been employed for the purposes of clarifying the sugar, is to be thoroughly washed with the purest water that can be obtained, in order to remove all the saccharine matter adhering to it. When the washing process has been completed, the charcoal is laid out to dry, either in the open air or in a suitable stove; and when perfectly free from moisture, it is to be separated into small pieces and sifted through a sieve, the wire or meshes of which are placed at distances of about two and a half in every inch. This sifting will not only divide the charcoal into small pieces, but will cause any bits of wood or other improper matters to be separated from it.

The charcoal thus prepared is then to be packed lightly in cylindrical vessels called crucibles, with some small quantity of bones, oil, or other animal matter, mixed with it. The crucibles are then closed by covers, and luted at the joints, leaving no other opening but one small hole in the centre of the cover, through which any gas generated within the vessel when placed in the oven or furnace may be allowed to escape.

The crucibles are now to be ranged round the oven, and placed one upon another, in vertical positions; and when the oven is properly heated, gas will be generated within each crucible, and issue out from the central hole. The gas thus emitted, being of an inflammable quality, will take fire, and assist in heating the crucibles; and the operation being carried on until the crucibles become of a red heat, the oven is then to be closed, and allowed to cool; after which the crucibles are to be removed, when the charcoal will be found to have become perfectly renovated, and as fit for use as before.

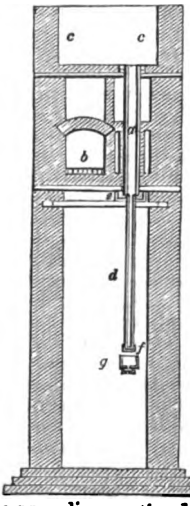
208



A process for the restoration of bone-black, or animal charcoal, was made the subject of a patent by Messrs. Bancroft and Mac Innes of Liverpool, which consists in washing the granular charcoal, or digesting it, when finely ground, with a weak solution of potash or soda, of specific gravity 1·06. The bone black which has been used in sugar refining may be thus restored, but it should be first cleared from all the soluble filth by means of water.

Mr. F. Parker's method, patented in June, 1839, for effecting a like purpose, is by a fresh calcination, as follows :—

Fig. 207 represents a front section of the furnace and retort; and *fig.* 208 a transverse vertical section of the same. *a* is a retort, surrounded by the flues of the furnace *b*; *c* is a hopper or chamber, to which a constant fresh supply of the black is furnished, as the preceding portion has been withdrawn, from the lower part of *a*. *d* is the cooling vessel, which is connected to the lower part of the retort *a* by a sand joint *e*. The cooler *d* is made of thin sheet iron, and is large; its bottom is closed with a slide plate, *f*. The black, after passing slowly through the retort *a* into the vessel *d*, gets so much cooled by the time it reaches *f*, that a portion of it may be safely withdrawn, so as to allow more to fall progressively down; *g* is the charcoal-meter, with a slide door.—H. M. N.

BONE OIL. See DIPPEL'S OIL.

BOOKBINDING. Books are said to be either *stitched*, or in *boards*, or *half-bound*, or *bound*. The first consists simply of stitching the sheets together. The second, of placing the sheets, after they have been stitched, between millboard sides, which are covered with paper or cloth, and with the backs lettered and ornamented. The third is a process of more perfectly securing the leaves, and of placing them between boards with a back of leather, the side-boards being covered with marble paper. Books are whole bound when the sides as well as back are covered with leather. Bookbinding is performed in the following manner :—The sheets are first folded into a certain number of leaves, according to the form in which the book is to appear as follows :—

The folio consists of	2	leaves
„ quarto of	4	„
„ octavo of	8	„
„ duodecimo of	12	„

When the leaves are thus folded and arranged in proper order, they are, if the books have been *long printed*, usually beaten upon a stone with a heavy hammer, to make them solid and smooth, and are then subjected to severe pressure in a powerful press; but in the case of newly-printed books, pressure alone is considered sufficient. Beating, or severe pressure, would spoil the book; because the ink, not being well dried, would "set off" on the opposite pages.

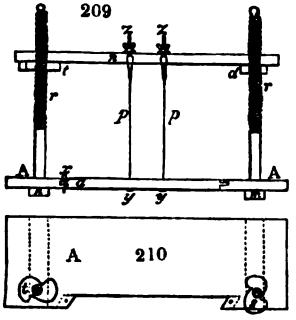
The employment in bookbinding of a rolling-press for smoothing and condensing the leaves, instead of the hammering which books have usually received, is an improvement introduced several years ago into the trade by Mr. W. Burn. His press consists of two iron cylinders about a foot in diameter, adjustable in the usual way by means of a screw, and put in motion by the power of one man, or of two if need be, applied to one or two winch handles. In front of the press sits a boy who gathers the sheets into packets, by placing two, three, or four upon a piece of tin plate of the same size, and covering them with another piece of tin plate; and thus proceeding by alternating tin plates and bundles of sheets till a sufficient quantity has been put together, which will depend on the stiffness and thickness of the paper. The packet is then passed between the rollers and received by the man who turns the winch, and who has time to lay the sheets on one side and to hand over the tin plates by the time that the boy has prepared a second packet. A minion bible may be passed

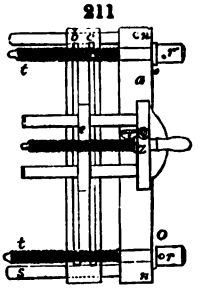
Digitized by Google

through the press in one minute, whereas the time necessary to beat it would be twenty minutes. It is not, however, merely a saving of time that is gained by the use of the rolling-press; the paper is made smoother than it would have been by beating; and the compression is so much greater, that a rolled book will be reduced to about five-sixths of the thickness of the same book if beaten. A shelf, therefore, that will hold fifty books bound in the usual way would hold nearly sixty of those bound in this manner — a circumstance of no small importance, when it is considered how large a space even a moderate library occupies, and that book-cases are expensive articles of furniture. The rolling-press is now substituted for the hammer by our principal bookbinders.

After the sheets have been thus prepared, they are sewed; for which purpose the sewing-press is employed.

Fig. 209 represents the sewing-press, as it stands upon the table, before which the bookbinder sits. *Fig.* 210 is a ground-plan without the parts *a* and *u* in the former figure. A is the base-board, supported upon the cross-bars *m n*, marked with dotted lines in *fig.* 210. Upon the screw rods *r r*, *fig.* 209, the nuts *t d* serve to fix the flat upper bar *n*, at any desired distance from the base. That bar has a slit along its middle, through which the hooks below *z z* pass down for receiving the ends of the sewing cords *p p*, fixed at *y y*, and stretched by the thumb-screws *z z*. The bar *y y* is let into an oblong space cut out of the front edge of the base-board, and fixed there by a movable pin *a*, and a fixed pin at its other end round which it turns. The cords or packthread, called "bands," are fixed at distances agreeably to certain saw-marks made in the backs of the sheets. The thread is drawn through the middle of each sheet and turned round each band, beginning at the first and proceeding to the last. The number of bands is usually six for folios, and five for quartos, three or four being employed for smaller sizes.





All the sheets being stitched together, and secured around the bands, the back is glued. The ends of the bands having been opened and scraped with a knife, they are, in common binding, pasted flatly upon the millboard sides; after which the back is beaten into a convex form with a hammer, the book being fixed in a press, between boards called backing boards, in order to form a groove for admitting the millboard sides. When the sides are applied in the better class of binding, holes are made in the millboard for drawing the bands through, the superfluous ends are cut off, and the parts are hammered smooth. The book is next pressed for cutting.

Fig. 211 is the bookbinder's cutting press, which is set upright upon a sort of chest for the reception of the paper shavings; and consists of three sides, being open above and to the left hand of the workman. The pressbar, or beam *a*, has two holes *n n* upon its under surface, for securing it to two pegs standing on the top of the chest. The screw rods *t t* pass through two tapped holes in the bar, marked *b c*, at its upper end; their heads *r r* being held by the shoulders *o o*. The heads are pierced with holes into which lever pins are thrust for screwing the rods hard up. The heavy beam *a* remains immovable, while the parallel bar with the book is brought home towards it by the two screws. The two rulers *s s* serve as guides to preserve the motions truly parallel; and the two parallel lath bars *b c* guide between them the end bar *e* of the plough, whose knife is shown at *i*, with its clamping screw *z*.

A machine for cutting the edges of books, bank-notes, &c., either truly square or polygonal, with mathematical precision, was patented by Mr. Wilson, and is much used, being known as Wilson's cutting machine or the millstone. *Fig.* 212 represents an end elevation of the machine; *fig.* 213, a side view of the same, the letters of reference indicating the same parts of the machine in each of the figures.

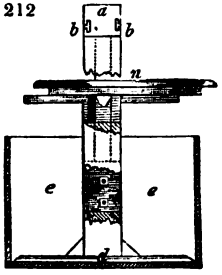
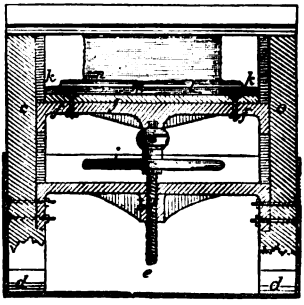
a is the top cross bar with rectangular grooves *b b*; *c c* are side posts; *d d* cross feet to the same, with strengthening brackets; *e e* a square box in which the press stands, for holding waste cuttings. *Fig.* 214 is a cross section of the upright posts *c c* taken horizontally. There are rectangular grooves in the upright posts, for the projecting ends of the cast-iron cross bracket *f* to slide up and down in. In the middle of the under side of this piece *f* there is a boss, within which is a round recess, to receive the top of the screw *g*, which works in the cast-iron cross piece *h*, similarly made with the former, but bolted firmly to the posts *c c*. Upon the screw *g* there is a circular

212

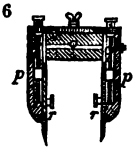


213



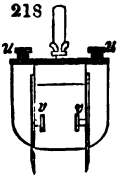
handle or ring *i*, for partially turning the screw, and immediately over it cross holes for tightening the press by means of a lever bar. Upon the cross piece *f* is bolted the board *j*, and upon each end of this board is made fast the rabbetted pieces *k k*, for another board *l* to slide in. Across the middle of this board, and parallel to the

216

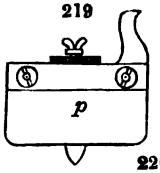


217

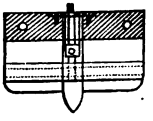
218



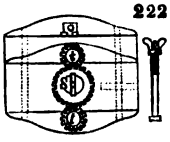
219



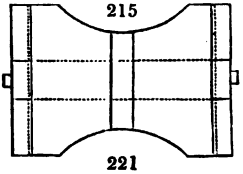
220



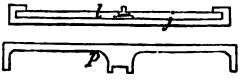
222



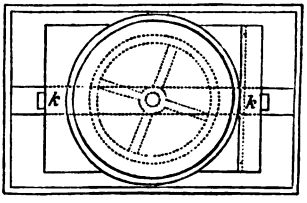
215



221



214



pieces *k k*, the tongue piece *m* is made fast, which fits into a groove at the bottom of board *l*. A horizontal representation of this is seen at *fig.* 215; and immediately under this view is also seen an end view of *l* and *f* connected together, and a side view of *f* by itself. In the middle of the board *l* is a pin for a circular board *n* to turn upon, and upon this latter board is placed the "material to be cut," with a saving piece between it, and the circular piece which is to be divided upon its edge into any number of parts required, with a stationary index on the board *l* to point to each.

It will now be understood that the material to be cut, may be turned round upon the centre pin of the board *n*, and also that both it and the board can be shifted backward and forward under the top cross piece *a*, and between the side slide slips *k k*, the surfaces of which should also be divided into inches and tenths.

Digitized by Google

The plough (*fig.* 216) is made to receive two knives or cutters, and which are situated in the plough in the following manner:—The plough is composed of three principal parts—namely, the top, and its two sides. The top, *o*, is made the breadth of the cross piece *a*, and with a handle made fast thereon. The sides, *p p*, are bolted thereto with bolts and nuts through corresponding holes in the top and sides. The figures give inside views and cross sections of the details of the manner in which the cutters and adjustments are mounted. A groove is cut down each cheek or side, in which are placed screws that are held at top and bottom from moving up and down, but, by turning, they cause the nuts upon them to do so; they are shown at *q q*. These nuts have each a pin, projecting inwards, that goes into plain holes made in the top ends of cutters *r r*.

The cutters and the work for causing them to go up and down are sunk into the cheeks, so as to be quite level with their inner surfaces. *Fig.* 217 shows one of those screws apart, how fixed, and with movable nut and projecting pin. The top of each screw terminates with a round split down, and above it a pinion-wheel and boss thereon, also similarly split. This pinion fits upon the split pin. Above, there is cross section of a hollow coupling cap, with steel tongue across, that fits into both the cuts of the screw pin and pinion boss, so that, when lowered upon each other, they must all turn together. In the middle and on the top of the upper piece, *o*, the large wheel, *s*, runs loose upon its centre, and works into the two pinion wheels, *t t*. The wheel *s* has a fly nut with wings mounted upon it.

It will now be seen, when the plough is in its place, as at *fig.* 218, that if it be pushed to and fro by the right hand, and the nut occasionally turned by the left, the knives, or cutters, will be protruded downwards at the same time, and these either will or will not advance as the coupling caps, *u u*, are on or off. The ribs, *v v*, run in the grooves, *b b* (*fig.* 212), and keep the cutters to their duty, working steadily. The top cross bar, *a*, is the exact breadth of a bank note, by which means both knives are made to cut at the same time. The paper is cut uniformly to one length and accurately square. By the use of this machine, the air-pump paper-wetting apparatus, and appendant press, the paper of 45,000 notes is fully prepared in one hour and a half by one person, and may then be printed. It is not so much injured by this process as by the ordinary method of clipping by hand, soaking it, &c. The wood-cuts to *fig.* 222 represent the plough in its different positions.

One of the improvements in the art of bookbinding is that for which Mr. William Hancock obtained a patent. After folding the sheets in double leaves, he places them vertically, with the edges forming the back of the book downwards, in a concave mould, of such rounded or semi-cylindrical shape as the back of the book is intended to have. The mould for this purpose consists of two parallel upright boards, set apart upon a cradle frame, each having a portion or portions cut out vertically somewhat deeper than the breadth of the book, but of a width nearly equal to its thickness before it is pressed. One of these upright boards may be slidden nearer to or farther from its fellow, by means of a guide-bar attached to the sole of the cradle. Thus the distance between the concave bed of the two vertical slots in which the book rests, may be varied according to the length of the leaves. In all cases about one-fourth of the length of the book at each end projects beyond the board, so that one-half rests between the two boards. Two or three packthreads are now bound round the leaves, thus arranged, from top to bottom of the page in different lines, in order to preserve the form given to the back by the mould in which it lay. The book is next subjected to the action of the press. The back, which is left projecting *very slightly* in front, is then smeared carefully by the fingers with a solution of caoutchouc, whereby each paper edge receives a small portion of the cement. In a few hours it is sufficiently dry to take another coat of a somewhat stronger caoutchouc solution. In 48 hours, four applications of the caoutchouc may be made and dried. The back and the adjoining part of the sides are next covered with the usual band or fillet of cloth, glued on with caoutchouc; after which the book is ready to have the boards attached, and to be covered with leather or parchment, as may be desired.

We thus see that Mr. Hancock dispenses entirely with the operation of stitching, sewing, sawing-in, hammering the back, or the use of paste and glue. Instead of leaves attached by thread stitches at two or three points, we have them agglutinated securely along their whole length. Books bound in this way open so perfectly flat upon a table, without strain or resilience, that they are equally comfortable to the student, the musician, and the merchant. The caoutchouc cement, moreover, being repulsive to insects and not affected by humidity, gives this mode of binding some superiority over the old method with paste or glue. For engravings, atlases, and ledgers, this binding is admirably adapted, because it allows the pages to be displayed most freely without the risk of dislocating the volume; but, for security,

Digitized by Google

three or four stitches should be made. The leaves of music books bound with caoutchouc, when turned over, lie flat at their whole extent, as if in loose sheets, and do not torment the performer like the leaves of the ordinary books, which are so ready to spring back again. Manuscripts and collections of letters which happen to have little or no margin left at the back for stitching them by, may be bound by Mr. Hancock's plan without the least encroachment on the writing. The thickest ledgers thus bound open as easily as paper in quire, and may be written on up to the innermost margin of the book without the least inconvenience.

An ingenious invention, for which Mr. Thomas Richards, of Liverpool, bookbinder, obtained a patent in April, 1842, is called by him "mechanical bookbinding." He employs, 1st, a mechanism to sew, weave, or bind a number of sheets together to form a book, instead of stitching them by hand; 2ndly, a table which slides to and fro to feed or supply each sheet of paper separately into his machine; also needle bars, or holders, to present needles with the requisite threads for stitching such sheets as they are supplied with in succession. He has, moreover, a series of holding fingers, or pincers, suitably provided with motions, to enable them to advance and clasp the needles, draw them through the sheets of paper, and return them into their respective holders after threading or stitching the sheet; lastly, there are arms, or levers, for delivering each sheet regularly upon the top of the preceding sheets, in order to form a collection or book of such sheets, ready for boarding or finishing. A minute description of the whole apparatus, with plates, is given in Newton's "Journal," C.S. xxiii. 157.

After the sides have been attached to the book, they have to be covered with leather. For this purpose, the prepared skin, moistened with water, is cut to the size of the book, and the thickness of the edge is pared off on a marble stone. It is next smeared over with paste made of wheat flour, stretched over the millboard on the outside, and doubled over the edges within. The book is then corded, that is, bound firmly betwixt two boards to make the cover adhere strongly to the millboard and the back, on the exact performance of which the neatness of the book in a great measure depends. The back is then warmed at the fire to soften the glue, and the leather is rubbed down with a bodkin or folding stick, to set and fixed it close to the back of the book. It is now set to dry, and, when dry, the boards are removed; the cover of the book is then washed or sprinkled over with a little paste and water, the edges then sprinkled with a fine brush, by striking it against the hand or a stick, or with large spots, by being mixed with the solution of green vitriol, or they are marbled. Two blank leaves are then pasted down to the cover, and the edges of the leaves, when dry, are burnished in the press, and the cover rolled on its edges. The cover is now glazed twice with the white of an egg, filleted, and, last of all, polished, by passing a hot iron over the glazed colour.

Nothing places in so striking a point of view the superior taste, judgment, and resources of London tradesmen over those of the rest of the world, than the extensive substitution which they have recently made of embossed silks and calicoes for leather in the binding of books. In old libraries, cloth-covered boards indeed may occasionally be seen, but they have the meanest aspect, and are in no respect to be compared with our modern cloth binding. The silk or calico may be dyed of any shade which use or fancy may require, impressed with gold or silver foil in every form, and variegated by ornaments in relief, copied from the most beautiful productions in nature. This new style of binding is distinguished not more for its durability, elegance, and variety, than for the economy and despatch with which it ushers the offspring of intellect into the world. For example, should a house eminent in this line receive 5000 volumes from Messrs. Longman and Co. upon Monday morning, they can have them all ready for publication within the incredibly short period of two days. The reduction of price is not the least advantage incident to the new method, amounting to fully 50 per cent. upon that with leather.

The dyed cloth being cut by a pattern to the size suited to the volume, is passed rapidly through a roller press, between engraved cylinders of hard steel, whereby it receives at once the impress characteristic of the back and the sides along with embossed designs over the surface in sharp relief. The cover thus rapidly fashioned is as rapidly applied by paste to the stitched and pressed volume, no time being lost in mutual adjustments, since the steel rollers turn off the former of a shape precisely adapted to the latter. Hard-glazed and varnished calico is moreover much less an object of depredation to moths and other insects than ordinary leather has been found to be.

BORACIC ACID. (*Acide Borique*, Fr. BO^3; chemical equivalent, 34·9; specific gravity, 1·83.) Supposed to be the *chrysocolla* of Pliny. In the seventh century. Geber mentions borax; and it was described by Geoffroy and by Baron in the early

Digitized by Google

part of the eighteenth century. Boracic acid was formerly called *Homberg's sedative salt.*

This acid occurs in several minerals, particularly as tincal, or crude biborate of soda, which is found in the form of incrustations in the beds of small lakes in Thibet, where it is dug up during the hot season. Sassolin, so called from its having been first obtained from one of the localities in Tuscany, named Sasso, is native boracic acid. It is found abundantly in the crater of Vulcano, one of the Lipari Islands, forming a layer on the sulphur and around the fumaroles, or exits, of the sulphurous exhalations. The native stalactitic salt, according to Klaproth, contains mechanically mixed sulphate of magnesia and iron, sulphate of lime, silica, carbonate of lime, and alumina. Erdmann has stated that sassolin contains 3·18 per cent. by weight of ammonia, and, instead of being pure boracic acid, that it is a borate of ammonia. Native boracic acid is composed of boracic acid, 56·4; water, 43·6.—*Dana.* See TINCAL.

Hayescine is another mineral containing boracic acid, which has been within the last few years imported in Liverpool from Peru. Hayescine is a borate of lime, having a composition of boracic acid. 45·46; lime, 14·32; soda, 8·22; potash, 0·51; sulphuric acid, 1·10; chloride of sodium, 2·65; sand, 0·32. This analysis was made by Mr. A. Dick in the metallurgical laboratory of the Museum of Practical Geology. It occurs over the dry plains of Iquique, in Southern Peru, in white reniform masses, from the size of a hazel nut to that of a potato, where it is called *tiza.*

In many other parts of South America, minerals containing boracic acid are known to exist; and they are said to be abundant in some parts of Brazil. The great supply of boracic acid, however, is derived from the Boracic Acid lagoons of Tuscany. Before the discovery of this acid, in the time of the Grand Duke Leopold I., by the chemist Hæfer, the fetid odour developed by the sulphuretted hydrogen gas and the disruptions of the ground occasioned by the appearance of new *suffioni*, or vents of vapour, had made the natives regard them as a diabolical scourge, which they sought to remove by priestly exorcisms; but since science has explained the phenomena, the *fumachi* have become a source of public prosperity, and, were they to cease, would be prayed to return. The vapours, containing a very minute quantity of boracic acid, which issue from the lakes in the lagoons of this volcanic district, keep the waters always at a boiling temperature; hence, after impregnation for 20 or 30 hours, by the steams pouring through the highest lake, the waters are drawn off into a second lake, to suffer a fresh impregnation. Thence they are drawn into a third, and so on, till they reach the lowest receptacle. In this passage they get charged with ½ per cent. of boracic acid. They are then concentrated in leaden reservoirs by the heat of the vapours themselves.

The liquid, after having filled the first compartment, is diffused very gradually into the second, then into the third, and successively to the last, where it reaches such a state of concentration that it deposits the crystallised acid, the workmen remove it immediately by means of wooden scrapers. This mode of gradual concentration is very ingenious, and requires so few hands, that it may almost be said that the acid is obtained without expense. From 1818 to 1845, the quantity of acid manufactured was 33,349,095 Tuscan pounds. From 1839 to 1845, the mean quantity has been 2,500,000 lbs.

Thus, in estimating the product at 7500 lbs. per day, the quantity of saturated water upon which they operate is 1,500,000 daily, and annually 547,500,000 lbs.

This labour brings to Tuscany 10,000,000 francs. It is surprising that it should have remained unproductive for so many ages, and that it should have been reserved for the skill of Count Larderel, of Monte Cerboli — before 1818 a simple wandering merchant, entirely unacquainted with scientific researches — to discover the nature of the fugitive vapours, and render them a source of inexhaustible wealth.

Professor Graham, in his "Report on the Chemical Products of the Great Exhibition of 1851," thus speaks of Larderel's discovery:—

"The preparation of boracic acid by Count F. de Larderel, of Tuscany, was rewarded by a Council medal. Although this well-known manufacture is not recent, having attained its full development at least ten years, still the bold originality of its first conception, the perseverance and extraordinary resources displayed in the successful establishment, and the value of the product which it supplies, will always place the operations of Count de Larderel among the highest achievements of the useful arts, and demand the most honourable mention at this epoch. The vapour issuing from a volcanic soil is condensed, and the minute proportion of boracic acid which it contains (not exceeding 0·3 per cent.) is recovered by evaporation, in a district without fuel, by the application of volcanic vapour itself as a source of heat. The boracic acid thus obtained greatly exceeds in quantity the old and limited supply of borax from the upper districts of India, and has greatly extended the use of that salt in the glazes of porcelain, and recently in the making of the most brilliant crystal, when

Digitized by Google

combined with the oxide of zinc instead of oxide of lead."—*Reports of the Jurors of the Great Exhibition of* 1851.

The violence with which the scalding vapours escape from the *suffioni* gives rise to muddy explosions when a lake has been drained by turning its waters into another lake. The mud is then thrown out, as solid matters are ejected from volcanoes, and there is formed in the bottom of the lake a crowd of little cones of eruption, whose temperatures when in activity and play are generally from 120° to 145° C., and the clouds which they form in the lagoons constitute true natural barometers, whose greater or less density rarely disappoints the predictions that they announce to the inhabitants of those lagoons.

The boracic acid of the Tuscan lagoons is obtained from nine different works belonging to Count Larderel:—Sasso, Larderello, Lervazano, Monte Cerboli, Castel Nuovo, Monte Rotondo, San Frederigo, Lustignano, Lago, producing 163,855 avoirdupois pounds per month.

Although the boracic acid in the lagoons of Tuscany was discovered in 1777 by Peter Hoeffer, apothecary to the Grand Duke of Tuscany, until 1818 all the efforts made to render it profitable to obtain it were of the most desultory character, and generally failures. In 1818 Count Lardarel established the first works at Monte Carboli, and used *artificial heat* to effect the evaporation. In 1828 they began to *use the natural heat of the soffioni to evaporate the boracic waters of the lagoons*, effecting thus an enormous saving and greatly extending the works.

Count Lardarel furnished Mr. W. P. Jervis with the following statement of the production of boracic acid, from the commencement of the works to the year 1859.

Society of Arts' Journal.

The following, amongst other minerals, are found amidst the Lagoons of Tuscany.

	Boracic Acid.	Lime.	Silica, Alumina, &c.	Sesquioxide of Iron.	Water.	Ammonia.
Sassoline - -	56·4	- -	- -	- -	43.6	- -
Hayescine - -	57·13	20·85	1·75	- -	26·25	- -
Lagonite - -	47·95	- -	1·77	36·26	14·02	- -
Lardarelite -	68·56	- -	- -	- -	18·32	12·73

Beyond these there is Mascagrine, composed of sulphuric acid 52·33, ammonia 4-67, and water 12·00. M. Payen has given the following as the composition of this crude boracic acid for 100 kilogrammes:—

Pure crystallised boracic acid - - - -	74 to 84
Sulphate of ammonia, magnesia, and lime - -	14 to 8
Sand and sulphur - - - - - -	2·5 to 1·25
Hygroscopic water disengaged at 35° C. - -	7 to 5·75
Azotic matter, hydrochlorate of ammonia, &c. -	2·5 to 1

The processes of chemical alteration taking place beneath the crater of Vulcano, already spoken of, may, according to the statement of Hoffmann, depend upon conditions very similar to those existing in Tuscany. There, likewise, sulphuretted hydrogen is associated with the boracic acid, and, it would appear, in much greater quantity, since the fissures through which the vapour issues are thickly lined with sulphur, which is in sufficient quantity to be collected for sale. A profitable factory is established at the place, which yields daily, besides boracic acid and chloride of ammonium, about 1700 lbs. of refined sulphur and about 600 lbs. of pure alum.—*Bischof.*

Foreign and Colonial produce exported 718 cwts. to the value of 1,795*l.*

BORAX. (*Borax*, Fr.; *Borar*, Germ.) A native saline compound of boracic acid and soda, found in Thibet, in China, in Persia, the island of Ceylon, and in South America; it has also been found in small quantities in Saxony. The crude product from the former locality was imported into Europe under the name of *tincal*, and was purified from some adhering fatty matter by a process kept a long time secret by the Venetians and the Dutch, and which consisted chiefly in boiling the substance in water with a little quicklime.

Gmelin found borax, in prismatic crystals, to contain 46·6 per cent. of water; and Arvredson gives as the composition of borax, in the calcined state, 68·9 of acid, and 31·1 soda, in 100 parts. M. Payen describes an octahedral borax, which contains only 30·64 per cent. of water, and is therefore preferred by the braziers in their soldering processes.

Anhydrous Borax, therefore, is composed of—

1 equivalent of boracic acid - - -	872	or	69·0
1 „ soda - - - - -	390	„	31·0
	1262	for	100·0

Octahedral Borax—

1 equivalent of boracic acid - - -	872	or	47·7
1 „ soda - - - - -	390	„	21·3
5 „ water - - - -	562·5	„	31·0
	1824·5	for	100·0

Prismatic Borax—

1 equivalent of boracic acid - - -	872	or	36·55
1 „ soda - - - - -	390	„	16·35
10 „ water - - - -	1·125	„	47·1
	2·387	for	100·00

Tincal was originally brought from a salt lake in Thibet; the borax was dug in masses from the edges and shallow parts of the lake; and in the course of a short time the holes thus made were again filled. The borate of soda has been found at Potosi, in Peru; and it has been discovered by Mr. T. Sterry Hunt, of the Geological Survey, in Canada, from whose report the following extract is made:—

"In the township of Joly there occurs a very interesting spring on the banks of the Ruisseau Magnenat, a branch of the Rivière Souci, about five miles from the mills of Methot at Saint Croix. The spring furnishes three or four gallons a minute of a water which is sulphurous to the taste and smell, and deposits a white matter along its channel, which exhibits the purple vegetation generally met with in sulphur springs. The temperature of this spring in the evening of one 7th of July was 46° F., the air being 52° F. The water is not strongly saline, but when concentrated is very alkaline and salt to the taste. It contains, besides chlorides, sulphates, and carbonates, a considerable proportion of boracic acid, which is made evident by its power of reddening paper coloured by turmeric, after being supersaturated with hydrochloric acid. . . . The analysis of 1000 parts of the water gave as follows:—

Chloride of sodium - - - - - -	0·3818
„ potassium - - - - - -	0·0067
Sulphate of soda - - - - - -	0·0215
Carbonate and borate of do. - - - - -	0·2301
„ of lime - - - - - -	0·0620
„ magnesia - - - - - -	0·0257
Silica - - - - - - - -	0·0245
Alumina - - - - - - - -	a trace
	0·7523

"The amount of boracic acid estimated was found to be equal to 0·0279."

Digitized by Google

Professor Bechi has analysed a borate occurring as an incrustation at the Tuscan lagoons, which afforded boracic acid 43·56, soda 19·25, and water 37·19. *Lagonite* is a mineral of an earthy yellow colour, which appears to be boracic acid and iron; while *Larderellite*, also from Tuscany, is a compound of boracic acid and soda. See *Dana*, and "American Journal of Science."

Borax has a sweetish, somewhat lixivial, taste, and affects vegetable colours like an alkali; it is soluble in 12 parts of cold and in 2 parts of boiling water. It effloresces and becomes opaque in a dry atmosphere; it appears luminous, by friction, in the dark. It melts at a heat a little above that of boiling water, and gives out its water of crystallisation, after which it forms a spongy mass, called calcined borax. The octahedral borax, which is prepared by crystallisation, in a solution of 1·255 specific gravity, kept up at 145° F., is not efflorescent. When borax is ignited, it fuses into a glassy-looking substance.

The following is the mode of purifying borax. The crude crystals are to be broken into small lumps, and spread upon a filter lined with a lead grating, under which a piece of cloth is stretched upon a wooden frame. The lumps are piled up to the height of 12 inches, and washed with small quantities of caustic soda lye of 5° B. (specific gravity 1·033) until the liquor comes off nearly colourless; they are then drained, and put into a large copper of boiling water, in such quantities that the resulting solution stands at 20° B. (specific gravity 1·160) Carbonate of soda equivalent to 12 per cent. of the borax must now be added; the mixed solution is allowed to settle, and the clear liquid is siphoned off into crystallising vessels. Whenever the mother waters get foul, they must be evaporated to dryness in cast-iron pots, and roasted, to burn away the viscid colouring matter.

The following process for refining the native Indian borax, or tincal, has been published by MM. Robiquet and Marchand:—

It is put into large tubs, covered with water for 3 or 4 inches above its surface, and stirred through it several times during six hours. For 400 lbs. of the tincal there must now be added 1 lb. of quicklime diffused through two quarts of water. Next day the whole is thrown upon a sieve, to drain off the water with the impurities, consisting, in some measure, of the fatty matter combined with the lime, as an insoluble soap. The borax, so far purified, is to be dissolved in 2½ times its weight of boiling water, and 8 lbs. of muriate of lime are to be added for the above quantity of borax. The liquor is now filtered, evaporated to the density of 18° or 20° B. (1·14 to 1·16 specific gravity), and set to crystallise in vessels shaped like inverted pyramids, and lined with lead. At the end of a few days, the crystallisation being completed, the mother waters are drawn off, the crystals are detached and dried. The loss of weight in this operation is about 20 per cent.

Borax is sometimes adulterated with alum and common salt: the former addition may be readily detected by a few drops of water of ammonia, which will throw down its alumina; and the latter by nitrate of silver, which will give with it a precipitate insoluble in nitric acid.

The native boracic acid obtained from the lakes of Tuscany, being manufactured in France into borax, has greatly lowered the price of this article of commerce. When MM. Payen and Cartier first began the business, they sold the crystals at the same price as the Dutch, viz., 7 francs the kilogramme (2¼ lbs. avoird.); but, in a few years, they could only obtain 2 francs and 60 centimes, in consequence of the market getting overstocked. The mode of making borax from the acid is as follows:—The lake water is evaporated in graduation houses, and then concentrated in boilers till it crystallises. In that state it is carried to Marseilles. About 1100 lbs. of water are made to boil in a copper, and 1320 lbs. of crystallised carbonate of soda are dissolved in it by successive additions of about 40 lbs. The solution being maintained at nearly the boiling point, 1100 lbs. of the crystallised boracic acid of Tuscany are introduced, in successive portions. At each addition of about 22 lbs. a lively effervescence ensues, on which account the copper should be of much greater capacity than is sufficient to contain the liquors. When the whole acid has been added, the fire must be damped by being covered up with moist ashes, and the copper must be covered with a tight lid and blankets, to preserve the temperature uniform. The whole is left in this state during 30 hours; the clear liquor is then drawn off into shallow crystallising vessels of lead, in which it should stand no higher than 10 or 12 inches, to favour its rapid cooling. At the end of three days in winter, and four in summer, the crystallisation is usually finished. The mother water is drawn off, and employed, instead of simple water, for the purpose of dissolving fresh crystals of soda. The crystals are carefully detached with chisels, redissolved in boiling water, adding for each 220 lbs. of borax, 22 lbs. of carbonate of soda. This solution marks 20° B. (specific gravity 1·160); and, at least, one ton of borax should be dissolved at

Digitized by Google

once, in order to obtain crystals of a marketable size. Whenever this solution has become boiling hot, it must be run off into large crystallising lead chests of the form of inverted truncated pyramids, furnished with lids, inclosed in wooden frames, and surrounded with mats to confine the heat. For a continuous business there should be at least 18 vessels of this kind, as the solution takes a long time to complete its crystallisation, by cooling to 30° C. (86° F.) The borax crystals are taken out with chisels, after the liquor has been drawn off and the whole has become cold.

One hundred parts of the purest acid, usually extracted from the lakes of Tuscany, contain only fifty parts of the real boracic acid, and yield no more, at the utmost, than 140 or 150 of good borax.

A considerable saving of expense in manufacturing borax, and a more ready application of the borax to use, has been proposed by Saulter, as follows:—Take about 38 parts of pure crystallised boracic acid, pounded and sifted; mix them well with 45 parts of crystals of carbonate of soda, in powder; expose the mixture upon wooden shelves to heat in a stove-room; and rake it up from time to time. The boracic acid and the alkali thus get combined, while the carbonic acid and water are expelled; and a perfect *dry borax* is obtained.

According to Wittstein, the commercial boracic acid is composed as follows:—

Sulphate of manganese	a trace
„ iron	0·365
„ alumina	0·320
„ lime	1·018
„ magnesia	2·632
„ ammonia	8·508
„ soda	0·917
„ potash	0·369
„ sal ammonia	0·298
„ silica (in solution)	1·200
„ sulphuric acid (combined with the boracic)	1·322
„ crystallisable boracic acid	76·494
Water	6·557
	100·000

Dry borax acts on the metallic oxides, at a high temperature, in a very remarkable manner, melting and vitrifying them into very beautiful coloured glasses. On this account it is a most useful reagent for the blowpipe. Oxide of chrome tinges it of an emerald green; oxide of cobalt, an intense blue; oxide of copper, a pale green; oxide of tin, opal; oxide of iron, bottle green and yellow; oxide of manganese, violet; oxide of nickel, pale emerald green. The white oxides impart no colour to it by themselves. In the fusion of metals, borax protects their surface from oxidisement, and even dissolves away any oxides formed upon them; by which twofold agency it becomes an excellent flux, invaluable to the goldsmith in soldering the precious metals, and to the brazier in soldering copper and iron.

Borax absorbs muriatic and sulphurous acid gases, but no others, whereby it becomes, in this respect, a useful means of analysis.

The strength or purity of borax may be tested by the quantity of sulphuric acid requisite to neutralise a given weight of it, as indicated by tincture of litmus.

When mixed with shellac in the proportion of one part to five, borax renders that resinous body soluble in water, and forms with it a species of varnish.

The applications of borax in the manufacture of enamels, glazes, and of glass, will be noticed in the articles devoted to the consideration of those special industries.

The importations of Borax in 1864 were :—

Borax Refined.

BORATE OF LIME. See DATHOLITE, HAYESINE.

BORATES. Salts of boracic acid. See Watts' "Dictionary of Chemistry."

BORING. The importance of boring, as a means of searching for coal and for water, renders it necessary that some special attention should be given to the subject in a work devoted to manufactures and mining.

Boring for water appears to have been in use from the earliest periods, in Egypt and in Asia. In many of the desert tracts there are remains of borings, which served, evidently, at one period, to supply the wants of extensive populations which once inhabited those now deserted regions. In the "Guide du Sondeur," by M. J. Degousée, we find it stated, with reference to China, "There exist in the canton of Ou-Tong-Kiao many thousand wells in a space of ten leagues long by five broad. These wells cost a thousand and some hundred taëls (the taël being of the value of 6*s.* 6*d.*), and are from 1500 to 1800 feet deep, and about 6 inches in diameter. To bore these wells, the Chinese commence by placing in the earth a wooden tube of 3 or 4 inches diameter, surmounted by a stone edge, pierced by an orifice of 5 or 6 inches; in the tube a trepan is allowed to play, weighing 300 or 400 lbs. A man, mounted on a scaffold, swings a block, which raises the trepan 2 feet high, and lets it fall by its own weight. The trepan is secured to the swing-lever by a cord made of reeds, to which is attached a triangle of wood; a man sits close to the cord, and at each rise of the swing seizes the triangle and gives it a half turn, so that the trepan may take in falling another direction. A change of workmen goes on day and night, and with this continuous labour they are sometimes three years in boring wells to the requisite depth."

Boring appears to have been practised in England during the last century, but to a very limited extent; it has, however, for a considerable period been employed in seeking for coal, and in the formation of ARTESIAN WELLS (*which see*).

The ordinary practice of boring is usually carried out, by first sinking a well of such a depth that the boring apparatus can be fixed in it; and thus a stage, raised from the surface of the ground, is dispensed with. A stout plank floor, well braced together by planks nailed transversely and resting on putlocks, forms the stage. In the centre of the floor is a square hole, through which the boring-rods pass. The boring-rods are of many different forms, some of which have been already described in the article on ARTESIAN WELLS. A few others are represented in the following figure (223).

1, 2, 3 are an elevation, plan, and section of an auger; the tapped socket is for the purpose of allowing the rods to be screwed into it.

4, 5 are two views of a small auger, with a longitudinal slit, and no valve, which is used for boring through clay and loam. In very stiff clay the slit is generally made larger; in moist ground the slit is objectionable.

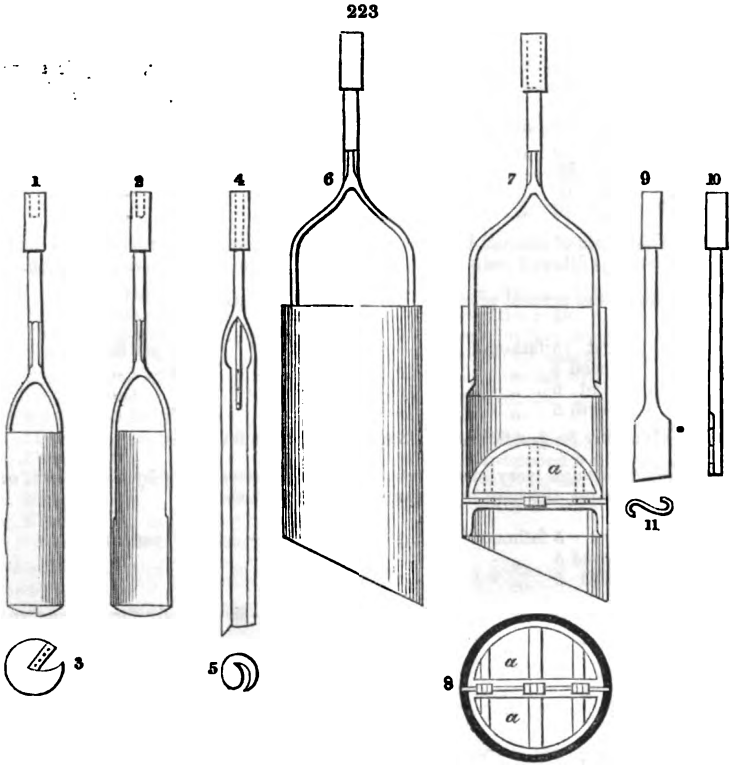
6, 7, 8 are different views of a shell. *a a* are valves opening upwards, to admit the material. These tools are used for boring through sand, or through ground which has been loosened by other tools.

9, 10, 11 show an S chisel, for cutting through rocks, flints, and the like.

Such are the principal tools employed. By referring to ARTESIAN WELLS, the general arrangement of the rods will be understood. The boring rods are turned round by the leverage of two handles moved by man, or, where the work is heavy, by horse, or sometimes, even steam power is applied. Besides the circular motion of the tool, a vertical percussive action of the same is required in certain cases, such as rock or hard sand; indeed, always, where the position of the augur or chisel requires a fresh place to act upon during its revolution. This motion is most readily got by suspending the boring rods to a windlass, through the intervention of a rope coiled two or three times round the latter, and adjusting it so that if the workman holds one end of the coil tight, sufficient will be the friction to raise the rods on putting the windlass

Digitized by Google

in motion. Should the end of the rope the workman holds now be slackened, the coil becomes loose, and the rods descend with a force equivalent to their weight and the distance through which they have fallen. A regular percussive action is thus gained by keeping the windlass continually in motion in one direction, the attendant workman alternately allowing the rods to be drawn up a certain distance, and then, by relaxing his hold, allowing them to fall. — *Swindell, on Boring.*



The following list of the prices of boring, in different localities, may prove useful :—

In the North of England, the prices for boring, in the ordinary strata of the district or of that coal field, are as follows :—

			s.	d.	
First	5	fathoms	5	6	per fathom.
Second	5	„	11	0	„
Third	5	„	16	6	„
Fourth	5	„	22	0	„

and so increasing 5*s.* 6*d.* per fathom on each succeeding depth of 5 fathoms. When any unusually hard strata are met with, the borer is paid by special arrangement, unless a binding contract has been previously made. It is sometimes usual for the borer to take all risk of hard strata, when the prices are as follows, the borer finding the tools : —

			s.	d.	
First	5	fathoms	7	6	per fathom.
Second	5	„	15	0	„
Third	5	„	22	6	„
Fourth	5	„	30	0	„

and so increasing 7*s.* 6*d.* per fathom on each succeeding depth of 5 fathoms.

Digitized by Google

In the Midland Counties, where the strata are more inclined than in the north of England, the prices for ordinary strata are as follows: —

			s.	d.	
First	20	yards	3	6	per yard.
Next	10	„	5	0	„
„	10	„	6	6	„
„	10	„	8	0	„
„	10	„	9	6	„

and so advancing 1*s.* 6*d.* per yard upon each 10 yards.

In some localities, where the boring is still more favourable, the prices are as follows, — the bore hole being $2\frac{1}{2}$ to $2\frac{3}{4}$ inches diameter: —

			s.	d.	
First	20	yards	3	6	per yard.
Next	10	„	4	6	„
„	10	„	5	6	„
„	10	„	6	6	„
„	10	„	7	6	„

In boring strata of unusual hardness a special arrangement is made, as before stated and the borer is allowed some payment for filling up and for removing tackling.

In Scotland the general prices for boring are as follows: —

			s.	d.	
First	5	fathoms	5	0	per fathom.
Second	5	„	10	0	„
Third	5	„	15	0	„
Fourth	5	„	20	0	„

and so advancing 5*s.* per fathom for each succeeding 5 fathoms.

In boring through very hard strata, the work is done either by shaft-work, or at the following rates, the bore hole being $2\frac{3}{4}$ inches diameter: —

			s.	d.	
First	5	fathoms	10	0	per fathom.
Second	5	„	20	0	„
Third	5	„	30	0	„

The borer usually specifies to have his tackle laid down ready for erecting at the cost of the employer.

As the boring proceeds, it is often necessary to lower pipes into the hole made, to prevent the falling of fragments from the sides of the cylinder. There are many ingenious contrivances for effecting this, which need not be described in this place.

Skill in boring judiciously for coal distinguishes the genuine miner from the empirical adventurer, who, ignorant of the general structure of coal-basins, expends labour, time, and money at random, and usually to no purpose; missing the proper coal-field, and leading his employer to sink a shaft where no productive seams can be had. A skilful coal-viewer, therefore, should always direct the boring operations, especially in an unexplored country.

The boring rods should be made of the best and most tenacious Swedish iron; in area, about an inch and a quarter square. Each rod is usually 3 feet long, terminating in a male screw at one end and a female screw at the other. The boring chisels are commonly 18 inches long, and from $2\frac{1}{2}$ inches to $3\frac{1}{4}$ inches at their cutting edge, which must be tipped with good steel. The chisel is screwed to an intermediate 18-inch rod, called the double-box rod, forming together a rod 3 feet long. There are, moreover, three short rods, a foot, 18 inches, and 2 feet long each, which may be screwed, as occasion requires, to the brace-head, to make the height above the mouth of the bore convenient for the hands of the men in working the rods. Hence the series of rods becomes a scale of measurement for noting the depth of the bore, and keeping a journal of the strata that are perforated. The brace-head rod, also 18 inches long, has two large eyes or rings at its top, set at right angles to each other, through which arms of wood are fixed for the men to lift and turn the rods by, in the boring process.

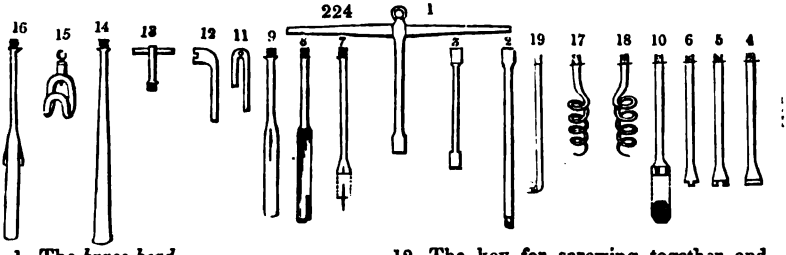
When the bore is intended to penetrate but a few fathoms, the whole work may be performed directly by the hands; but when the bore is to be of considerable depth, a lofty triangle of wood is set above the bore-hole, with a pulley depending at its summit angle, for conducting the rope to the barrel of a windlass or wheel and axle, secured to

Digitized by Google

the ground with heavy stones. The loose end of the rope is connected to the rods by an oval iron ring, called a runner; and by this mechanism they may be raised and let fall in the boring; or the same effect may be more simply produced by substituting for the wheel and axle a number of ropes attached to the rod-rope, each of which may be pulled by a man, as in raising the ram of the pile-engine.

In all the coal districts there are professional master-borers, who undertake to search for coal, and furnish an accurate register of the strata perforated.

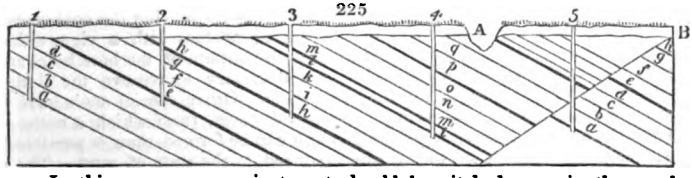
The boring tools employed in the coal districts are represented in the following plan (*fig.* 224):—



1. The *brace-head.*
2. The common rod.
3. The double-box rod; intermediate piece.
4. The common chisel.
5. The indented chisel.
6. Another of the same.
7. The cross-mouthed chisel.
8. The wimble.
9. The sludger, for bringing up the mud.
10. The rounder.
11. The key for supporting the train of rods at the bore-mouth.
12. The key for screwing together and asunder the rods.
13. The topit, or top piece.
14. The beché, for catching the rod when it breaks in the bore.
15. The runner, for taking hold of the topit.
16. The tongued chisel.
17. The right-handed worm screw.
18. The left-handed ditto.
19. The finger-grip or catch.

We shall now explain the manner of conducting a series of bores in searching ground for coal.

Fig. 225 represents a district of country in which a regular survey has proved the existence and general distribution of coal strata, with a dip to the south, as here



shown. In this case, a convenient spot should be pitched upon in the north part of the district, so that the successive bores put down may advance in the line of the dip. The first bore may therefore be made at No. 1, to the depth of sixty yards. In the progress of this perforation, many diversities and alternations of strata will be probably passed through, as we see in the sections of the strata; each of which, as to quality and thickness, is noted in the journal, and specimens are preserved. This bore is seen to penetrate the strata *d*, *c*, *b*, *a*, without encountering any coal. Now, suppose that the dip of the strata be one yard in ten, the question is, at what distance from bore No. 1, in a south direction, will a second bore of 60 yards strike the first stratum, *d*, of the preceding? The rule obviously is, to multiply the depth of the bore by the dip—that is, 60 by 10—and the product 600 gives the distance required; for, by the rule of three, if 1 yard of depression corresponds to 10 in horizontal length, 60 yards of depression will correspond to 600 in length. Hence the bores marked 1, 2, 3, 4, and 5, are successively distributed as in the figure, the spot where the first is let down being regarded as the point of level to which the summits of all the succeeding bores are referred. Should the top of No. 2 bore be 10 yards higher or lower than the top of No. 1, allowance must be made for this difference in the operation; and hence a surface-level survey is requisite. Sometimes ravines cut down the strata, and advantage should be taken of them, when they are considerable.

In No. 2 a coal is seen to occur near the surface, and another at the bottom of the

Digitized by Google

bore; the latter seam resting on the first stratum *d*, that occurred in bore No. 1; and No. 2 perforation must be continued a little farther, till it has certainly descended to the stratum *d*. Thus these two bores have, together, proved the beds to the depth of 120 yards.

No. 3 bore, being placed according to the preceding rule, will pass through two coal-seams near the surface, and after reaching to nearly its depth of 60 yards, it will touch the stratum *h*, which is the upper stratum of bore No. 2; but since a seam of coal was detected in No. 2, under the stratum *h*, the proof is confirmed by running the borer down through that coal. The field has now been probed to the depth of 180 yards. The fourth bore is next proceeded with, till the two coal-seams met in No. 3 have been penetrated; when a depth of 240 yards has been explored. Hence No. 4 bore could not reach the lower stratum *a*, unless it were sunk 240 yards.

The fifth bore (No. 5) being sunk in like manner, a new coal-seam occurs within a few yards of the surface; but after sinking to the depth at which the coal at the top of the fourth bore was found, an entirely different order of strata will occur. In this dilemma, the bore should be pushed 10 or 20 yards deeper than the 60 yards, to ascertain the alternations of the new range of superposition. It may happen that no coals of any value shall be found, as the figure indicates, in consequence of a slip or dislocation of the strata at B, which has thrown up all the coals registered in the former borings to such an extent that the strata *b*, *a*, of the first bore present themselves immediately on perforating the slip, instead of lying at the depth of 300 yards (5 × 60), as they would have done had no dislocation intervened. Some coal-fields, indeed, are so intersected with slips as to bewilder the most experienced miner, which will particularly happen when a lower coal is thrown upon one side of a slip, directly opposite to an upper coal situated on the other side of it; so that if the two seams be of the same thickness, erroneous conclusions are almost inevitable.

When a line of bores is to be conducted from the dip of the strata towards their outcrop, they should be placed a few yards nearer each other than the rule prescribes, lest the strata last passed through be overstepped, so that they may disappear from the register, and a valuable coal-seam may thereby escape notice. In fact, each successive bore should be so set down, that the first of the strata perforated should be the last passed through in the preceding bore; as is exemplified by viewing the bores in the retrograde direction, Nos. 4, 3, and 2. But if the bore No. 2 had gone no deeper than *f*, and the bore No. 1 been as represented, then the stratum *e*, with its immediately subjacent coal, would have been overstepped, since none of the bores would have touched it; and they would have remained unnoticed in the journal, and unknown.

Modifications required for deep boring.—In cases where it is necessary to carry a bore hole down to a great depth, as for example, in deep artesian wells, or in searching for coal under the new red sandstone or other rocks overlying the coal measures, special modifications are required in the boring apparatus, with a view either to diminish the force of impact of the tool against the bottom of the bore hole, and to save time in withdrawing it when it becomes necessary to remove the sludge or comminuted material produced during the boring. Other special tools have been introduced for the purpose of bringing up solid cores, from which a more exact opinion of the nature of the rock passed through can be formed, than is possible from the inspection of the same substance when reduced to the state of mud. The most essential of these improvements consists in the substitution of a heavy cutting instrument, attached by means of a slide bar and guide frame to the lower end of the boring rods. When the tool rests on the bottom of the hole, at the end of its stroke, a pair of clips at the top of the guide frame take hold of the neck of the tool, so that it is raised with the rods during their up stroke. When the highest point is reached, the clips let go their hold, and the tool falling alone, delivers its blow against the ground, the guide frame and slide bar ensuring a truly perpendicular motion. Several different methods are employed for releasing the tool, but the principal is in all cases similar, namely, that of delivering the blow with a constant force, and independently of the weight due to the increased length of the rods. The above system is known as boring with a free falling cutter, and was introduced in Prussia by Mr. Kind. For very deep bore holes it is customary to substitute wooden rods strengthened with wrought iron, instead of solid iron ones, so that when the bore hole is filled with water, a very considerable part of the dead weight to be moved is balanced off, during the lifting and withdrawal of the rods. Thus, for example, at the deep boring for salt executed at Schöningen, in Brunswick, by Mr. Kind, to a depth of 2,013 feet, the wooden rods employed weighed only 0·94 lbs., about fifteen ounces to the foot, in water, whereas a wrought iron rod would have weighed about 3¼ lbs. per foot, under the same circumstances. In order to expedite the withdrawal and replacement of the tool and rods, before and after the sludge is removed by the shell, it is necessary

Digitized by Google

to build a shed or tower at the surface, of sufficient height to take several lengths of rods joined together, so as to prevent any unnecessary unscrewing or screwing together. The shell (fig. 6, p. 409), is usually raised and lowered by a rope worked by a windlass and brake.

The instrument used for bringing up samples of the rock bored through, consists of four narrow chisels fixed to the ends of two intersecting wrought iron arms attached to the boring rod, which are covered both externally and internally by wrought iron tubes; the cutting is done by percussion, the portion of the ground between the two tubes being reduced to mud by the chisels, while the central portion, equal in diameter to the inner tube, is left untouched. The core is removed by a tool consisting of a tube open at both ends, and fixed to a four-armed crutch similar to that of the cutter; one arm, however, has a band of wrought iron attached to it, so as to form a spring, sufficient space being left between the arm and spring to admit a very taper sliding wedge. When this tool is lowered to within a few inches of the bottom, the core being within the tube, the rod is dropped suddenly when the wedge is driven home against the arm, and the tube, becoming distorted by compression, takes hold of the core, which may then be brought up unbroken. If it is desired to determine the dip of the rock bored through, from the specimen brought up, care must be taken to note the position of the rods, so that in unscrewing them the carrier may always be turned through one or more *entire* revolutions, and not through fractions of a revolution.

A method of boring with hollow rods, combined with a force pump, was introduced about the year 1846 by Mr. Fauvelle, in order to obviate the necessity of using the shell, the detritus produced by the tool being removed continuously by a downward current of water forced by the pump through the interior of the rod, and rising in the annular included space between the exterior of the rod and the lining tube. In spite of the apparent advantages of this method, namely, the maintenance of a clear face of rock for the cutting tool to work on, and the saving of time due to the abolition of the shell, and the adoption of the method of continuous discharge, it does not appear to have come much into use. Recently, however, a modification in which the discharge of the detrition is effected by an upward current of water through the rod, has been employed to advantage in borings for petroleum in Western Canada.

Bore holes of great diameter. Bored shafts.—Of late years several attempts have been made to sink shafts in wet ground, by means of boring tools, but although attended with a certain amount of success, this method has not been adopted to any great extent. The following is a general outline of the method adopted by Mr. Kind for boring a shaft at Stirrigen, in the department of the Moselle. A guide bore of 28 inches diameter was kept three fathoms in advance of the shaft, a hole of 15 feet diameter, for facilitating the collection of the sludge produced. The main boring tool was a long horizontal bar of wrought iron, about 14 feet long, armed with a great number of straight chisels about 5 inches length of cutting edge, which were attached to the rod by one upright bar in the centre, and two diagonal ones at either end. A little below the point of junction of the suspension bars with the rod was fixed a guide, consisting of a transverse wooden bar, terminated at either end by a short sector corresponding to the curvature of the side of the shaft. The weight of the whole of the cutting apparatus was about 3½ tons. In a newer machine used in Belgium, the bar carrying the chisels is made of Krupp's cast steel. The comminuted stuff, produced by the working of the large bore, was collected by a shell of the ordinary pattern, a wrought iron cylinder 14 feet long, and 6 feet diameter, suspended in the lower bore hole, such portion as remained on the floor of the shaft at the end of each spell of boring, being swept down into the shell by a rotary drag or scraper. The borer was worked by a steam engine of 20 horse-power, and the work proceeded at the rate of about 10 inches in 12 hours.

The Chinese method of boring with ropes instead of rigid rods has been tried at different times in Europe, but without any great amount of success, the system of rigid suspension being preferred for working, not only the cutting tool, but also the shell. A very important modification of this principle has, however, been introduced by Messrs. Mather and Platt of Salford, who have succeeded in carrying bores of considerable size (8 or 10 inches in diameter) to depths of 1200 feet and upwards. The whole of the arrangements employed are of a novel and simple character, the rope employed is a flat wire one, similar to those employed for drawing heavy loads in collieries, and is coiled on a drum with projecting horns, worked by a steam engine, so that it can be paid out as the depth increases. The cutting or boring head is attached to the end of the rope, and is actuated by a vertical steam engine, whose piston rod, passing through the top cover, is forked and carries a guide pulley over which the rope passes from the drum before it assumes the vertical position over the bore hole. When the work is commenced, sufficient rope is paid off the drum to allow the tool to touch the ground, when the engine is at the lowest point of its stroke; the rope is then fixed by a clamp screw, interposed between the drum and the

Digitized by Google

guide pulley, on the engine. Steam is admitted below the piston, which rises together with its rod and the top guide pulley, whereby the rope is lifted, and with it the boring tool. In order to prevent the piston from being twisted in its course, the rod is made square, and passes through a stuffing box of a similar form. The arrangement for motion resembles that of the loose pulley of an ordinary block tackle; the length of stroke on the outer side of the rope is double that of the engine. The arrangement of the valves of the engine is similar in principle to those of a single acting steam hammer; when the top of the stroke is reached, the exhaust valve is opened, and the down stroke is made by the gravitating action of the rope and its attached boring head. In order to prevent injurious shocks on the engine, the exhaust port is placed a short distance above the bottom of the cylinder, so that a portion of steam is intercepted by the descending piston, forming an elastic cushion, which stops it in its descent. The boring head is a heavy bar, terminating below in a hollow crown bore, formed of a ring of straight edged chisels curved outwards, and above is a square part which is twisted into a spiral. The link at the end of the rope carries a square frame, corresponding in form to the upper part of the bar, but somewhat shorter, so that it forms a kind of vertical sliding joint. When the engine commences its up stroke, the first effect is to cause the frame at the end of the suspension link to pass over the twisted head of the bar, thereby communicating a partial twist to the rope, which when the whole weight hangs loose tends to straighten itself, and turns the borer by a corresponding amount in the opposite direction. In order that this effect, produced by the twisting of the rope, may be always effective, a system of ratchet wheels is introduced below the top piece, allowing it to turn freely, while the tool is jammed in the ground at the end of the stroke, but preventing the parts from moving separately when the whole is freely suspended. The shell or sludge-pump used in this system of boring, also differs considerably from that generally used; it is, in fact, a complete lifting pump, having a hollow bucket with india-rubber valves working in a tube with foot valves of the ordinary pattern. When in position for lowering, it is suspended by a loop forming the bucket rod, so that the piston is at the top of the stroke. On reaching the bottom, however, it descends by its own weight, and is then worked by the engine drawing on the rope in the same way as an ordinary lifting pump. In this way, the removal of the detritus, one of the most difficult points in rope boring, is satisfactorily effected, and the work proceeds with considerable speed, as no change of suspension is required, as is the case in boring with the rods, the same rope carries both the tool and shell, the winding engine being brought into action by simply releasing the clamp screw, which keeps the rope in position during the period of boring.

Machines for boring and drilling rocks.—Among the most important applications of machinery, for the purposes of mining, is the more or less successful substitution of hand labour in the sinking holes for blasting in rocks, a subject which has received a considerable amount of attention during the past two or three years, both in this country, as well as in the continent of Europe, and in the United States. The method of action of these machines is substantially the same as that of those already described for boring wells and other vertical holes, but the motion of the tool, instead of being dependent on the rods, is produced by steam pressure acting upon a piston moving in a cylinder, which is directly connected with the borer, the cylinder and tool curves being mounted upon a frame provided with jerk screws for fixing it firmly, and positive and appropriate contrivances for the forward feed, and rotation of the cutter.

Sommeillier's machine.—This, the most extensively employed of all rock boring machines, is in use in the drivage of the tunnel on the Franco-Italian Railway, through Mont Cenis, in the Savoy Alps. It consists of a cast iron frame, about 9 feet long, formed of two parallel bars, connected at intervals by transverse pieces, which carries the cylinder, and is capable of being adjusted horizontally, or at any angle to the face of the rock. The cylinder is 2·4 inches in diameter, and is provided with a piston whose rod passes through both cylinder covers, and the front portion ending in a socket which carries the borer, while the hinder one is connected with the valve motion; the two portions of the rod are of different thicknesses, that in front having the largest section; the length of stroke of the piston is about 8 inches. The driving power, air compressed to about 75 lbs. on the square inch, is admitted and exhausted from the cylinder by three passages, two of these near the hinder end, forming exhaust and admission parts, are alternately opened and shut by a slide valve in the ordinary way, while the third, which is in the forward end, is constantly open and in communication with the vessel containing air at the maximum of pressure, so that the force of the forward blow is proportional to the difference of effective area between the two sides of the piston; only 100 lbs. being exerted to draw back the borer, while the blow is struck under an impulse of 240 lbs. A smaller auxiliary engine, attached to the hinder part of the frame, works the slide valve as well as the

Digitized by Google

rotation of the borer, the latter being effected by a ratchet pawl gearing into a wheel with 16 teeth, attached to the back part of the piston rod, one tooth being shifted at each stroke of the valve, so that the cutting edge of the borer makes one complete revolution in every sixteen blows. The feed, or forward motion of the cylinder as the hole deepens, is effected by a screw or worm wheel on the back piston rod, which gears into segments of a corresponding hollow or female screw formed in the long sides of the frame. As it is necessary, however, that this motion should be intermittent and dependent only on the progress of the work, the worm wheel is placed loose on the piston rod, and is only brought into action by a spring, which, in its turn, is kept back by a sliding rod provided with a detent which locks into the teeth of a rack placed below the frame. When the borer no longer reaches the face of the rock, a tappet on the piston rod releases the detent on the rod, whereby the worm wheel is pressed home against its bearing on the piston rod, and the cylinder is carried forward until the detent falls into the next tooth of the rack, and the machine is locked fast, having travelled through a distance of 1·4 inches, the length of stroke of the piston being reduced by the same amount, until the hole has been deepened by a corresponding quantity. The comminuted rock produced during the boring, is continuously removed by a jet of water, which is squirted into the hole under a pressure of 75 lbs. to the square inch. This precaution is found to be productive of great economy in the wear of the tools, as two holes can now be bored with the same borer, whereas formerly two or three drills were worn out in a single hole. Three different borers are employed for each hole, varying in length from 20 inches to 6½ feet, the distance through which the machine is capable of travelling on its bed plate is about 32 inches. Under ordinary conditions, the working speed is about 200 strokes per minute, at which rate from 8 to 10 holes of 1·6 inches diameter, and 35 inches deep can be bored in the shift of six hours. The tunnel is of an ⌂ shaped section, 13 feet broad and 9¾ feet high; 8 machines are employed at one time, they are mounted on a wrought iron frame, weighing about 15 tons, which travels on a railway, and can be removed to a safe distance when the blasting takes place. From 65 to 70 holes are bored in the face of the rock, and then loaded with uniform charges, made up into cartridges, are primed with fuses of different lengths, so as to explode in groups at definite intervals; a horizontal series at about mid-height is first fired, then follow two vertical side rows, then a group near the crown of the arch, and finally a horizontal series near the floor. In this way, the rock is blown down in nearly uniform fragments, of from 6 to 8 inches in the side. The work advances from 10 inches to 13 feet per day, according to the hardness of the rock.

Schumann's machine, which has been tried in the Saxon mines, is somewhat similar to that of Sommeillier, but is more direct in the valve motion, the slide being driven by gearing wheels connected with the piston rod, instead of employing an auxiliary engine; the feed motion is, however, less perfect, and is not self-acting. Another difference consists in the substitution of a worm wheel and screw for the ratchet motion employed in rotating the bores. Under the small pressure of 30 lbs. per square inch, this machine bored at the rate of 18 inches in 19 minutes.

Crease's machine, like Sommeillier's, has two cylinders, but they are placed side by side, and connected by passages so arranged that the pistons, of which there are two to each cylinder, act alternately as valves to each other. The feed or forward motion of the borer is effected by connecting the feed screw to the spindle at the back of the main cylinder, by fixing on the screw a ratchet wheel with lever and pawl, working loose on the same, or by connecting this lever with an eccentric fixed on the spindle. The feed may be varied at pleasure by altering the distance from the centre of the ratchet wheel and feed screw, at which the lever is connected to the eccentric.

Gwynne's boring machine.—This machine, which is used in driving the Hoosack tunnel, in New Hampshire, is distinguishable from those already noticed, by having a tubular piston rod, so arranged that the boring tool, or drill, can be drawn out and replaced from behind, without in any way altering the position of the machine or its framing, when at work. The cylinder is suspended in its frame by an universal joint, consisting of a pair of trunnions mounted on cylindrical bearings, giving a vertical motion, which, in their turn, are provided with slides, forming circular segments, which travel in beds of a corresponding form, attached to the upright of the frame. By means of this arrangement, the cylinder can be adjusted at any angle of elevation, and within a considerable angle laterally, but there is no forward motion, the advancing depth of the hole being met by the use of longer drills, up to a length of 4½ feet, which is the greatest depth of hole that can be bored. The driving power employed is steam of 120 lbs. pressure to the square inch, a maximum speed of 1200 strokes per minute having been attained experimentally. As in Sommeillier's machine, a stream of water from a small force pump is employed to wash the detritus continuously out of the bore hole.

Digitized by Google

Leschot's rock drilling machine.—The whole of the preceding examples of boring machines are contrived in imitation of the process of hand boring, the borer or drill acting by percussive impact against the face of the rock, and producing a volume of powdered rock equal to the solid contents of the bore hole. A machine has, however, been recently introduced by Mr. Leschot, of Geneva, in which the cutting tool is of a tubular form, and receives an uniform rotating motion, the result being the production of an annular groove with a solid cylindrical core corresponding to the hollow of the tube, which, when broken out, gives a bore hole of the proper size, while the amount of rock pulverised is only equal to the solid contents of the tubular cutter. The general principles of the construction of this machine are as follows. The cutter is a short wrought iron tube of $1\frac{1}{2}$ inches diameter, and about $\frac{1}{4}$ inch thick, carrying at one end a series of fragments of Brazilian black diamond, such as are used by lapidaries for cutting diamonds, rubies, and other gems. These fragments are placed at intervals of about $\frac{1}{8}$ of an inch apart, both inside and outside the tube, the projection above the surface of the metal being not more than $\frac{1}{50}$th of an inch. The cutter is attached by a bayonet clutch to a hollow wrought iron tube, carried in a wrought iron frame, having a long screw cut on the opposite end, which travels in a nut carried in a collar in the hinder part of the frame. A horizontal shaft, which receives motion from the driving wheel by means of a pair of bevel wheels, is fixed parallel to the boring tube, it carries two spur wheels, one of which gears into a similar wheel, fixed about midway between the forward end of the feed screw, and the front of the frame, while the other is in connection with the nut. These wheels are not of uniform diameters, and are arranged in pairs, so as to produce a slight difference in speed between the tube and the nut, the cutting end of the tube being carried forward with a slow grinding action, due to the differential motion so produced. The hole is cleaned by a jet of water which is brought through a flexible hose attached to the back of the boring tube by a swivel joint, in order that it may not be twisted by the rotation of the latter. A machine worked by the extreme power of two men, at 30 revolutions per minute, bored holes in granite $1\frac{1}{4}$ inches diameter, at the rate of from 9 to 10 inches per hour. The amount of rock pulverised was equal to rather less than one half of the solid contents of the finished bore hole. The continually increasing price of the diamonds forming the cutters, will probably prevent this ingenious machine coming into extensive use; the wear is, however, said to be very small. A boring head of the dimensions given above, costs from 5*l.* to 6*l.*, and when the points are worn down, they are still available for lapidaries' use.

BORON. One of the non-metallic elements; it exists in nature in the form of boracic acid, and as borax, tincal, &c.

Homberg is said to have obtained boron from borax in 1702; if so, his discovery appears to have been forgotten, since it was unknown, except hypothetically, to the more modern chemists until, in 1808, it was obtained by Gay-Lussac and Thénard, and by Davy in 1808, who decomposed boracic acid into boron and oxygen.

Boron is best obtained by preparing the double fluoride of boron and potassium ($3KF\ 2BF^3$), by saturating hydrofluoric acid with boracic acid, and then gradually adding fluoride of potassium. The difficultly soluble double compound thus produced is collected and dried at a temperature nearly approaching to redness. This compound is then powdered and introduced into an iron tube closed at one end, together with an equal weight of potassium, whereupon heat is applied sufficient to melt the latter, and the mixture of the two substances is effected by stirring with an iron wire. Upon the mass being exposed to a red heat, the potassium abstracts the fluorine. The fluoride of potassium may afterwards be removed by heating the mass with a solution of chloride of ammonium, which converts the free potassa into chloride of potassium, and thus prevents the oxidation of the boron, which takes place in the presence of fixed alkali; the chloride of ammonium adhering to the boron may be afterwards removed by treatment with alcohol. Boron is a dark greenish-brown powder, tasteless, and inodorous; its chemical equivalent is 11·0. See GRAPHITOIDAL and DIAMOND BORON.—*Watts' Dictionary of Chemistry.*

BOTTLE MANUFACTURE. See GLASS and STONE WARE.

BOUGIE. A smooth, flexible, elastic, slender cylinder, introduced into the urethra, rectum, or œsophagus, for opening or dilating it, in cases of stricture and other diseases. The invention of this instrument is claimed by Aldereto, a Portuguese physician; but its form and uses were first described by his pupil Amatus, in the year 1554. Some are solid and some hollow, some corrosive and some mollifying. They owed their elasticity, as formerly made, to linseed oil, inspissated by long boiling, and rendered dry by litharge. This viscid matter was spread upon a very fine cord or tubular web of cotton, flax, or silk, which was rolled upon a slab, when it became nearly solid by drying, and was finally polished.

Pickel, a French professor of medicine, published the following recipe for the com-

Digitized by Google

position of bougies. Take 3 parts of boiled linseed oil, 1 part of amber, and 1 of oil of turpentine; melt and mix these ingredients well together, and spread the compound at 3 successive intervals upon a silk cord or web. Place the pieces so coated in a stove heated to 150 F.; leave them in it for 12 hours, adding 15 or 16 fresh layers in succession, till the instruments have acquired the proper size. Polish them first with pumice-stone, and finally smooth with tripoli and oil. This process is the one still employed in Paris, with some slight modifications; the chief of which is dissolving in the oil one-twentieth of its weight of caoutchouc, to render the substance more solid. For this purpose the caoutchouc must be cut into slender shreds, and added gradually to the hot oil. The silk tissue must be fine and open, to admit of the composition entering freely among its filaments. Every successive layer ought to be dried in a stove, and then in the open air, before another is applied. This process takes 2 months for its completion, in forming the best bougies called by distinction *elastic bougies;* which ought to bear twisting round the finger without cracking or scaling, and extension without giving way, but retracting when let go. When the bougies are to be hollow, a mandrel of iron wire, properly bent, with a ring at one end, is introduced into the axis of the silk tissue. Some bougies are made with a hollow axis of tinfoil rolled into a slender tube. Bougies are now usually made entirely of caoutchouc, by the intervention of a solution of this substance in sulphuric ether, a menstrum sufficiently cheap in France, on account of the low duty upon alcohol, or of naphtha. There are medicated bougies, the composition of which belongs to surgical pharmacy. The manufacture of these instruments of various kinds forms a separate and no inconsiderable branch of industry at Paris. Very superior bougies are now made by the surgical-instrument makers, and by the workers in caoutchouc, in this country.

BOULDER CLAY. In commercial language, the fine laminated clays of the Pleistocene epoch, which immediately overlie the true *Boulder clay* of geologists—so called from the boulders and pebbles interspersed through their mass.

BOULDERING STONE. A name given by the Sheffield cutlers to the smooth flint pebbles with which they smooth down the faces of buff and wooden wheels.

BOURNONITE. A sulphide of antimony, lead, and copper. According to Rammelsbery, sulphur 19·76, antimony 24·34, lead 42·88, copper 13·06. It is found in several parts of Cornwall and Devonshire, and in most of the mining districts of Europe.

BOVEY COAL. See LIGNITE.

BOX WOOD. (*Buis*, Fr.; *Buchsbaum*, Germ.) *Buxus sempervirens.*—Two varieties of box wood are imported into this country. The European is brought from Leghorn, Portugal, &c.; and the Turkey box wood from Constantinople, Smyrna, and the Black sea. English box wood grows plentifully at Box Hill, in Surrey, and in Gloucestershire. The English box wood is used for common turnery, and is preferred by brass finishers for their lathe-chucks, as it is tougher than the foreign box, and bears rougher usage. It is of very slow growth, as in the space of 25 years it will only attain a diameter of 1½ to 2 inches. Box wood is used for making clarionets and flutes, carpenters' rules, and drawing scales, and is exclusively employed by the wood engraver. Its sawdust is used for cleaning jewellery. See ENGRAVING ON WOOD.

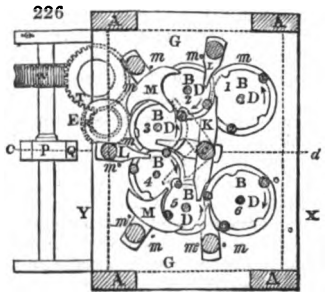
BRACES (*Bretelles*, Fr.; *Hosenträger*, Germ.) Narrow fillets or bands of leather or textile fabrics, which pass over the shoulders, and are attached behind and before to the waistbands of trousers, for supporting their weight. Braces are now made of an elastic material, into the structure of which Indian-rubber fibre enters.

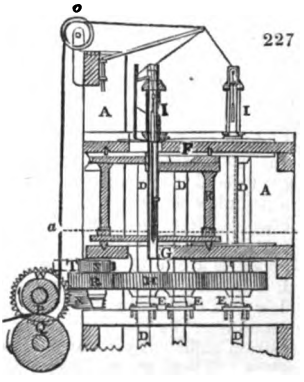
BRAID. A plaited, twisted or woven trimming.

BRAIDING MACHINE (*Machine à lacets*, Fr.; *Bortenwirkerstuhl*, Germ.) This being employed, not only to manufacture stay-laces, braid, and upholsterers' cord, but to cover the threads of caoutchouc for weaving brace-bands, deserves a description in this work. Three threads at least are required to make such a knitted lace, but 11, 13, or 17, and even 29 threads are often employed, the first three numbers being preferred. They are made by means of a frame of a very ingenious construction which moves by a continuous rotation. We shall describe a frame with 13 threads, from which the structure of the others may be readily conceived. The basis of the machine consists of four strong wooden uprights, A, *fig.* 226, 227, 228, occupying the four angles of a rectangle, of which one side is 14 inches long, the other side 18 inches, and the height of the rectangle about 40 inches. *Fig.* 226 is a section in a horizontal plane, passing through the line *a b* of *fig.* 227, which is a vertical section in a plane passing through the centre of the machine C, according to the line *c d*, *fig.* 226. The side X is supposed to be the front of the frame; and the opposite side, Y, the back. B, six spindles or skewers, numbered from 1 to 6, placed in a vertical position upon the circumference of a circle whose centre coincides with that of the machine at the point C. These six spindles are composed—1, Of so many iron shafts or axes D, supported in brass collets E (*fig.* 227), and extended downwards within 6 inches of the ground, where they rest in brass steps fixed upon a horizontal beam. 2, Wooden heads, made of horn-beam

Digitized by Google

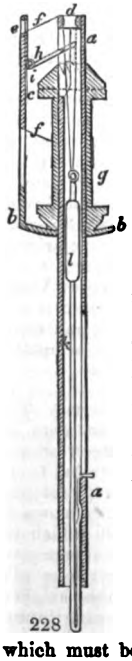
or nut-tree, placed, the first upon the upper end of each spindle, opposite the cut-out beam F, and the second opposite the second beam G. 3, Wooden-toothed wheels, H,





reciprocally working together, placed between the beam G and the collet-beam E. The toothed wheels and the lower heads for each spindle are in one piece.

The heads and shafts of the spindles No. 1 and 6 are one-fifth stronger than those of the other spindles; their heads have five semi-circular grooves, and wheels of 60 teeth, while the heads of the others have only four grooves, and wheels of 48 teeth; so that the number of the grooves in the six spindles is 26, one-half of which are occupied with the stems of the puppets I, which carry the 13 threads from No. 1 to 13.



The toothed wheels, which give all the spindles a simultaneous movement, but in different directions, are so disposed as to bring their grooves opposite to each other in the course of rotation.

K, the middle winglet, triple at bottom and quintuple at top, which serves to guide the puppets in the direction they ought to pursue.

L, three winglets, single at top and bottom, placed exteriorly, which serve a like purpose.

M, two winglets, triple at bottom and single at top, placed likewise exteriorly, and which serve the same purposes as the preceding; *m*, are iron pins inserted in the cut-out beam G, which serve as stops or limits to the oscillations of the exterior winglets.

Now, if by any moving power (a man can drive a pair) rotation be impressed upon the large spindle No. 1, in the direction of the arrow, all the other spindles will necessarily pursue the rotatory movement indicated by the respective arrows. In this case the 13 puppets working in the groves of the heads of the spindles will be carried round simultaneously, and will proceed, each in its turn, from one extremity of the machine to the opposite point, crossing those which have a retrograde movement. The 13 threads united at the point N, situated above the centre of the machine, will form at that point the braid, which after having passed over the pulley *o*, comes between the two rollers P Q, and is squeezed together, as in a flatting-mill, where the braid is calendered at the same time that it is delivered. It is obvious that the roller P, receives its motion from the toothed wheel of the spindle No. 3, and from the intermediate wheels, R, S, T, as well as from the endless screw *z*, which drives at proper speed the wheel W, fixed upon the shaft of the roller P.

The braid is denser in proportion as the point N is less elevated above the tops of the puppets, but in this case, the excentric motion of these puppets is much more sensible in reference to that point towards which all the threads converge than when it is elevated. The threads, which must be always kept equally stretched by means of a weight, as we shall presently see, are considerably strained by the traction occasioned by the constantly excentric movement of the puppets. From this cause, braiding machines must be worked at a moderate velocity. In general, for fine work, 30 turns of the large spindle per minute are the utmost that can safely be made.

The puppet or spindle of this machine, being the most important piece, I have represented it in section, upon a scale one-fourth of its actual size, *fig.* 228. It is formed of a tube, *a*, of strong sheet iron well brazed; *b* is a disc, likewise of sheet iron, from which a narrow fillet, *c*, rises vertically as high as the tube, where both

Digitized by Google

are pierced with holes, *d e*, through which the thread *f* is passed, as it comes from the bobbin, *g*, which turns freely upon the tube *a*. The top of this bobbin is conical and toothed. A small catch or detent, *h*, movable in a vertical direction round *i*, falls by its own weight into the teeth of the crown of the bobbin, in which case this cannot revolve; but when the detent is raised so far as to disengage the teeth, and at the same time to pull the thread, the bobbin turns, and lets out thread till the detent falls back into these same teeth.

A skewer of iron wire, *k*, is loaded with a small weight, *l*, melted upon it. The top of this skewer has an eye in it, and the bottom is recurved, as is shown in *fig.* 228, so that supposing the thread comes to break, this skewer falls into the actual position in the figure, where we see its lower end extending beyond the tube *a*, by about ¼ of an inch; but as long as the thread is unbroken, the skewer *k*, which serves to keep it always tense during the excentric movement of the puppet, does not pass out below the tube.

This disposition has naturally furnished the means of causing the machine to stop whenever one of the threads breaks. This inferior protrusion of the skewer pushes in its progress a detent, which instantly causes the band to slide from the driving pulley to the loose pulley. Thus the machine cannot operate unless all the threads be entire. It is the business of the operative, who has 3 or 4 under her charge, to mend the threads as they break, and to substitute full bobbins for empty ones, whenever the machine is stopped.

BRAHMIN'S BEADS. The seeds of a species of *Elæocarpus*, which are capped with silver and made into necklaces and bracelets.

BRAN. (*Son*, Fr.; *Kleie*, Germ.) The husky portion of ground wheat, separated by the boulter from the flour. It is advantageously employed by the calico printers, in the clearing process, in which, by boiling in bran-water, the colouring matters adhering to the non-mordanted parts of maddered goods, as well as the dun matters which cloud the mordanted portions, are removed. A valuable series of researches by M. Daniel Kœchlin-Schouch, justified the following conclusions:—

1. The dose of 2 bushels of bran for 10 pieces of calico is the best, the ebullition being kept up for an hour. A boil for the same time in pure water had no effect in clearing either the grounds or the figures.

2. Fifteen minutes' boiling are sufficient when the principal object is to clear white grounds, but in certain cases 30 minutes are requisite to brighten the dyed parts. If, by increasing the charge of bran, the time of the ebullition could be shortened, it would be, in some places, as Alsace, an economy; because in the passage of the 10 pieces through a copper or vat heated with steam, 1 cwt. of coal is consumed in fuel, which costs from 2½ to 3 francs, while 2 bushels of bran are to be bought for 1 franc.

3. By increasing the quantity of water from 12 to 24 hectolitres with 2 bushels of bran, the clearing effect upon the 10 pieces was impaired. It is therefore advantageous not to use too much water.

4. Many experiments concur to prove that flour is altogether useless for the clearing boil, and that finer bran is inferior for this purpose to the coarser.

5. The white ground of the calicoes boiled with wheat bran is distinguishable by its superior brightness from that of those boiled with rye bran, and especially with barley bran; the latter having hardly any effect.

6. There is no advantage in adding soap to the bran boil; though a little potash or soda may be properly introduced when the water is calcareous.

7. The pellicle of the bran is the most powerful part; the flour and the starch are of no use in clearing goods, but the mucilage, which forms one-third of the weight of the bran, has considerable efficacy, and seems to act in the following way. In proportion as the mucilaginous substance dissolves the colouring and tawny matters upon the cloth, the husky surface attracts and fixes upon itself the greater part of them. Accordingly, when used bran is digested in a weak alkaline bath, it gives up the colour which it had absorbed from the cloth.

From bran, Péligot obtained 8·0 per cent. of cellulose. Millon succeeded in extracting considerable quantities of glutinous substances from the bran with acetic acid and alcohol. He found in 100 parts, starch, dextrine, and sugar, 50·0; sugar, 1·0; gluten, 14·9; fat, 3·6; cellulose, 9·7; salts, 5·7; water, 13·9; and of odorous and resinous matters, 1·2 per cent.

BRANDS. Imperfectly carbonised pieces of wood taken from a charcoal heap.

BRANDY. (*Eau de Vie*, Fr.; *Branntwein*, Germ.) The name given in this country to ardent spirits distilled from wine, and possessing a peculiar taste and flavour, due to a minute portion of a volatile oil. Each variety of alcohol has an aroma characteristic of the fermented substance from which it is procured; whether it be the grape, cherries, sugar-cane, rice, corn, or potatoes; and it may be distinguished even as procured from different growths of the vine. The brandies of

Digitized by Google

Languedoc, Bordeaux, Armagnac, Cognac, Aunis, Saintonge, Rochelle, Orleans, Barcelona, Naples, &c., being each readily recognisable by an experienced dealer.

Aubergier showed, by experiments, that the disagreeable taste of the spirits distilled from the *marc* of the grape is owing to an essential oil contained in the skin of the grape; and found that the oil, when insulated, is so energetic that a few drops are sufficient to taint a pipe of 600 litres of fine-flavoured spirit. See FUSEL OIL.

The most celebrated of the French brandies, those of Cognac and Armagnac, are slightly rectified to only from 0·935 to 0·922: they contain more than half their weight of water, and come over therefore highly charged with the fragrant essential oil of the husk of the grape. When, to save expense of carriage, the spirit is rectified to a much higher degree, the dealer, on receiving it at Paris, reduces it to the market proof by the addition of a little highly-flavoured weak brandy-and-water; but he cannot in this way produce so finely-flavoured a spirit as the weaker product of distillation of the Cognac wine. If the best Cognac brandy be carefully distilled at a low heat, and after distillation the strong spirit be diluted with water to restore it to its original strength, it will be found that the brandy has suffered much in its flavour.

Genuine French brandy evinces an acid reaction with litmus paper, owing to a minute portion of vinegar; it contains, besides, some acetic ether, and, when long kept in oak casks, a little astringent matter.

The constituents of brandy are *alcohol*, *water*, *volatile oil*, *acetic acid*, *acetic ether*, *colouring matter*, and *tannin*.—*Pereira*.

Pale brandy acquires the slight colour which it possesses from the cask in which it is kept. *Brown brandy* is coloured by *caramel*. Brandy is sold of various strengths, but it is usually about 10 per cent. under proof. The quantities of brandy imported since 1860, and its computed value, have been as follows:—

	1860	1861	1862	1863	1864
Gallons - - - - -	2,342,543	2,097,934	2,375,835	3,132,293	4,907,770
Computed real value	£1,088,177	£930,538	£1,031,182	£1,124,824	£1,505,382
Average price (exclusive of duty	9*s.* 6½*d.*	9*s.* 1*d.*	9*s.* 1*d.*	7*s.* 6½*d.*	

The duty on brandy was reduced in 1860 to 8*s.* 6*d.* per gallon.

BRANDY, BRITISH. Dr. Ure gave the following formulæ for its preparation:—Dilute pure alcohol to the proof pitch; add to every hundred pounds weight of it from half a pound to a pound of argol, dissolved in water, a little acetic ether, and French wine vinegar, some bruised French plums, and flavour stuff from Cognac; then distil the spirit with a gentle fire in an alembic furnished with an agitator. British brandies are now sold as pure grain spirits, flavoured and coloured with caramel. See ALCOHOL.

BRASS. (*Laiton*, *cuivre jaune*, Fr.; *Messing*, Germ.) An alloy of copper and zinc. The brass of the ancients appears, in very early times, to have chiefly consisted of a mixture of copper and tin, and to have, consequently, been a species of bronze or bell metal. See ALLOYS.

Brass was formerly manufactured by cementing granulated copper, called *bean-shot*, or copper clippings, with calcined calamine (native carbonate of zinc) and charcoal in a crucible, and exposing them to bright ignition. Three parts of copper were used for 3 of calamine and 2 of charcoal. James Emerson obtained a patent, in 1781, for making brass by the direct fusion of its two metallic elements, and it is now usually manufactured in this way.

It appears that the best proportion of the constituents to form fine brass is 2 equivalents of copper = 63½ + 1 of zinc = 32·3; or very nearly 2 parts copper to 1 of zinc.

In the process of alloying two metals of such different fusibilities as copper and zinc, a considerable waste of the latter metal by combustion might be expected; but, in reality, their mutual affinities seem to prevent the loss, in a great measure, by the speedy absorption of the zinc into the substance of the copper. Indeed, copper plates and rods are often *brassed* externally by exposure, at a high temperature, to the fumes of zinc, and afterwards laminated or drawn. The spurious gold wire of Lyons is made from such rods. Copper vessels may be superficially converted into brass by boiling them in dilute muriatic acid containing some tartar and zinc amalgam.

The first step in making brass is to plunge slips of copper into melted zinc till an alloy of somewhat difficult fusion be formed, to raise the heat, and add the remaining proportion of the copper.

The brass of the first fusion is broken to pieces, and melted with a fresh quantity of zinc, to obtain the finished brass. Each melting takes from 8 to 9 hours. The metal is now cast into plates, about 40 inches long by 26 broad, and from one-third to half an inch thick. The moulds are, in this case, slabs of granite mounted in an iron frame. Granite appears to be preferred as a mould, because it preserves the

Digitized by Google

heat, whilst, by the asperities of its surface, it keeps hold of the clay lute applied to secure the joinings.

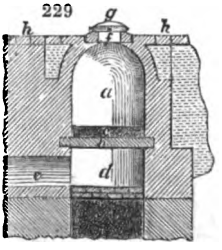
The cast plates are usually rolled into sheets. For this purpose they are cut into ribands of various breadths, commonly about 6½ inches. The cylinders of the brass rolling mill are generally 46 inches long, and 18 inches in diameter. The ribands are first of all passed through the cylinders cold; but the brass soon becomes too hard to laminate. It is then annealed in a furnace, and, after cooling, is passed afresh through the rolls. After paring off the chipped edges, the sheets are laminated two at a time; and if they are to be made very thin, even 8 plates are to passed through together. The brass in these operations must be annealed 7 or 8 times before the sheet arrives at the required thickness. These successive heatings are expensive; and hence manufacturers have been led to try various plans of economy. The annealing furnaces are of two forms, according to the size of the sheets of brass. The smaller are about 12 feet long, with a fire-place at each end, and about 13 inches wide. The arch of the furnace has a cylindrical shape, whose axis is parallel to its small side. The hearth is horizontal, and is made of bricks set on edge. In the front of the furnace there is a large door, which is raised by a lever, or chain and counterweight, and slides in a frame between two cheeks of cast iron. This furnace has, in general, no chimney, except a vent slightly raised above the door, to prevent the workmen being incommoded by the smoke. Sometimes the arch is perforated with a number of holes. The sheets of brass are placed above each other, but separated by parings, to allow the hot air to circulate among them, the lowest sheet resting upon bars of cast iron placed lengthwise.

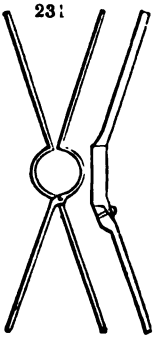
The larger furnaces are usually 32 feet long, by 6½ feet wide, in the body, and 3 feet at the hearth. A grate 13 inches broad extends along each side of the hearth, through its whole length, and is divided from it by a small wall, 2 or 3 inches high. The vault of the furnace has a curvature, and is pierced with 6 or 8 openings, which allow the smoke to pass off into a low bell-chimney above. At each end of the furnace is a cast-iron door, which slides up and down in an iron frame, and is poised by a counterweight. On the hearth is a kind of railway, composed of two iron bars, on which the carriage moves with its load of sheets of brass.

These sheets, being often 24 feet long, could not be easily moved in and out of the furnace; but as brass laminates well in the cold state, they are all introduced and moved out together. With this view an iron carriage is framed with bars, which rest on four wheels. Upon this carriage, of a length nearly equal to that of the furnace, are laid the sheets, with brass parings between them. The carriage is then raised by a crane to a level with the furnace, and entered upon the grooved bars which lie upon the hearth. That no heat may be lost, two carriages are provided, the one being ready to put in as the other is taken out; the furnace is meanwhile uniformly kept hot. This method, however convenient for moving the sheets in and out, wastes a good deal of fuel in heating the iron carriage.

The principal places in which brass is manufactured on a large scale, in England, are Bristol and Birmingham, and at Holywell, in North Wales.

At the brass manufactory of Hegermaül, upon the Finon Canal, near Potsdam, the following are the materials of one charge: 41 pounds of old brass, 55 pounds refined copper (*Gaarkupfer*) granulated, and 24 pounds of zinc. This mixture, weighing 120 pounds, is distributed in four crucibles, and fused in a wind furnace with pitcoal fuel. The waste, upon the whole, varies from 2½ to 4 pounds.





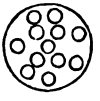


Fig. 229 represents the furnace as it was formerly worked with charcoal; *a*, the laboratory, in which the crucibles were placed. It was walled with fire bricks. The foundations and the filling-in walls were formed of stone rubbish, as being bad conductors of heat; sand and ashes may be also used; *b*, cast-iron circular grating plates, pierced with 12 holes (see *fig.* 230), over them a sole of loam, *c*, is beaten down, and perforated with holes corresponding to those in the iron discs; *d*, the ash-pit; *e*, the *bock*, a draught flue which conducts the air requisite to the combustion, from a sunk tunnel in communication with several melting furnaces. The terrace or crown of the furnace, *f*, lies on a level with the foundry floor, *h h*, and is shut with a tile of fire-clay, *g*, which

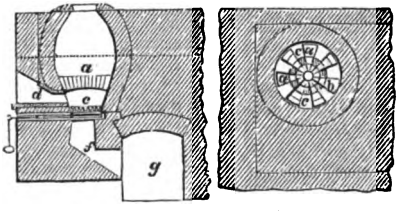
Digitized by Google

may be moved in any direction by means of hooks and eyes in its binding iron ring. *Fig.* 231 the tongs for putting in and taking out the charges, as viewed from above and from the side.

The following description of a continental brass manufactory, well described by Dr. Ure, it has been thought advisable to retain, with only a few verbal alterations.

Figs. 232, 233 represent the furnaces more recently constructed for the use of pitcoal fuel; *fig.* 232 being an upright section, and *fig.* 233 the ground plan. In this furnace the crucibles are not surrounded with the fuel, but receive the requisite melting heat from the flame proceeding from the grate upon which it is burnt. The crucibles stand upon seven arches *a*, which unite in the middle at the key-stone, *b*, *fig.* 233; between the arches are spaces through which the flame rises from the grate, *c*; *d*, is the fire door; *e*, a sliding tile or damper for regulating or shutting off the air-draught; *f* an inclined plane, for carrying off the cinders that fall through the grate, along the draught tunnel *g*, so that the air in entering below may not be heated by them.

232 233



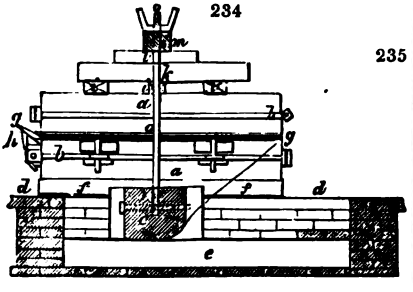
The crucibles are 16 inches deep, 9½ wide at the mouth, 6½ at the bottom; with a thickness in the sides of 1 inch above and 1½ below; they stand from 40 to 50 meltings. The old brass, which fills their whole capacity, is first put in and melted down; the crucibles are now taken out and charged with the half of the zinc in pieces of from 1 to 3 cubic inches in size, covered over with coal ashes; then one-half of the copper charge is introduced; again dust; and thus the layers of zinc and copper are distributed alternately with coal-ashes betwixt them, till the whole charge becomes finally fused. Over all, a thicker layer of carbonaceous matter is laid, to prevent oxidation of the brass. Eight crucibles filled in this way are put into the furnace between the 12 holes of the grate; and over them are laid two empty crucibles to be heated for the casting operation. In from 3½ to 4 hours the brass is ready to be poured. Fifteen English bushels of coals are consumed in one operation; of which six are used at the introduction of the crucibles, and four gradually afterwards.

When sheet brass is to be made, the following process is pursued:—

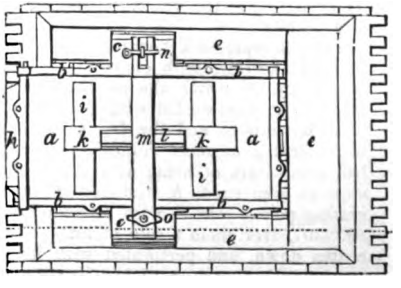
An empty crucible is taken out of the furnace through the crown with a pair of tongs, and kept red hot by placing it in a hollow hearth surrounded with burning coals; into this crucible the contents of four of the melting pots are poured; the dross is raked out with an iron scraper. As soon as the melting pot is emptied, it is immediately re-charged in the manner above described, and placed in the furnace. The surface of the melted brass is swept with the stump of a broom, and then stirred about with the iron rake, to bring up any light foreign matter to the surface, which is then skimmed with a little scraper; the crucible is now seized with the casting tongs, and emptied in the following way:—

The mould or *form* for casting sheet brass consists of two slabs of granite, *a a*, *figs.* 234, 235. These are 5½ feet long, 3 feet broad, 1 foot thick, and, for greater security,

234



235



girt with iron bands, *b b*, 2 inches broad, 1½ thick, and joined at the four corners with bolts and nuts. The mould rests upon an oaken block, *c*, 3½ feet long, 2½ broad, and 1¼ thick, which is suspended at each end upon gudgeons, in bearing blocks, placed under the foundry floor, *d d*, in the casting pit, *e e*. This is lined with bricks; and is 6¾ feet long, 5½ broad, and 2 deep; upon the two long side walls of the pit are laid the bearing blocks which support the gudgeons. The swing blocks are 10 inches long, 18 inches broad, 15 inches thick, and somewhat rounded upon their back edge.

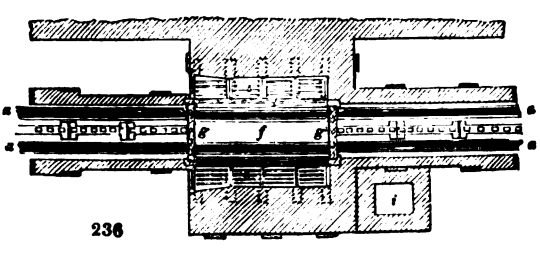
Digitized by Google

so that the casting frame may slope a little to the horizon. To these blocks two cross wooden arms, *f f*, are mortised, upon which the under slab rests freely, but so as to project about 5 inches over the block backwards, to secure an equipoise in the act of casting. *g g* are bars, placed at both of the long sides, and one of the ends, between the slabs, to determine the thickness of the brass-plate. Upon the other slab the gate *h* is fastened, a sheet of iron 6 inches broad, which has nearly the shape of a parallel trapezium (lozenge), and slopes a little towards the horizon. This serves for setting the casting pot upon in the act of pouring, and renders it more convenient to empty. The gate is coated with a mixture of loam and hair. The upper slab is secured to the under one in its slanting position by an *armour* or binding. This consists of tension bars of wood, *i*, *k*, *l*, *m*, of the iron bars *n*, (3 to 3½ inches broad, 1½ inch thick, see the top view, *fig.* 235) of a rod with holes and pins at its upper end, and of the iron screw spindle *o*. The mode in which these act may be understood from inspection of the figure. In order to lift the upper slab from the under one, which is effected by turning it round its edge, a chain is employed, suspending two others, connected with the slab. The former passes over a pulley, and may be pulled up and down by means of a wheel and axle, or the aid of a counterweight. Upon each of the two long sides of the slab are two iron rings, to which the ends of the chains may be hooked. The casting faces of the slab must be coated with a layer of finely ground loam; the thinner this is the better.

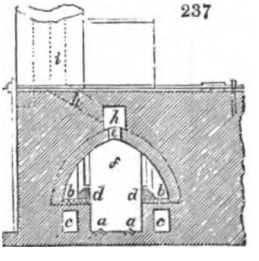
When calamine is employed, ½ cwt. of copper, ¾ cwt. of calamine, and ⅓rd the volume of both of charcoal mixed, are put into seven crucibles, and exposed to heat during 11 or 12 hours; the product being from 70 to 72 lbs. of brass.

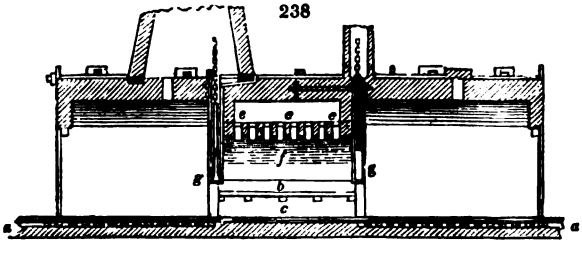
Brass-Plate Rolling.—At Hegermühl there are two re-heating or annealing furnaces, one larger, 18 feet long, and another smaller, 8½; the hot chamber is separated from the fireplace by iron beams, in such a way that the brass castings are played upon by the flames on both their sides. After each passage through the laminating rolls, they are heated anew, then cooled and laminated, until they have reached the proper length. The plates are smeared with grease before rolling.

Fig. 236 shows the ground plan of the furnace and its railway; *fig.* 237, the cross section; and *fig.* 238, the section lengthwise; *a a*, the iron way bars or rails upon



236





the floor of the foundry for enabling the wheels of the waggon to move rapidly backwards and forwards; *b b*, the two grates; *c c*, the ash pits; *d d*, the fire beams; *e e e*, vents in the roof of the hot chamber *f*; *g g*, two plates for shutting the hot chamber; *h*, the flue; *i*, the chimney. After rolling, the sheets, covered with black oxide of copper, are plunged for a few minutes into a mother water from the alum works, then washed in clean water, and lastly, smeared with oil, and scraped with a blunt knife.

For musical purposes, the brass wire of Berlin had acquired great and merited celebrity; but that of Birmingham and of Cheadle is now preferred by foreigners.

The following Table, for the compilation of which we are indebted to Mr. Robert Mallet, C.E., presents, in a very intelligible form, the chemical and physical conditions of the various kinds of brass:—

BRASS, MALLEABLE. It is known that common brass, containing from 27·4 to 31·8 per cent. of zinc and from 71·9 to 65·8 per cent. of copper, is not malleable while hot, but that articles of it must be made by casting. As it would be of great advantage in many branches of industry to have an alloy of this kind that could be worked while hot, like malleable iron, the information that such an alloy exists must be welcome to artists.

By melting together 33 parts of copper and 25 parts of zinc, there was a loss of 3 parts, thus making 60 per cent. copper and 40 per cent. zinc. It differs from the English specimens by containing a larger proportion of zinc, and possesses, according to M. Machts, the proprietor of a brass foundry in Hanover, the precious property of malleability in a higher degree than the English specimens.

A piece of "yellow metal," similar in colour to this alloy, was found on analysis to contain 60·16 copper and 39·71 zinc, which is the composition of malleable brass. It also showed great density or solidity.

An alloy was prepared by melting together 60 parts copper and 40 parts zinc, which had the following properties:—The colour was between that of brass and tombak, it had a strong metallic lustre, a fine close-grained fracture, and great solidity (density). Its specific gravity at the temperature of 10° C. was 8·44; by calculation it ought only to have been 8·08; thus showing that in the formation of the alloy a condensation must have taken place. Calculation shows that the alloy may be considered as a determinate chemical combination, for the results of the analysis very nearly accord with the assumption that it may be considered as composed of three atoms by weight of copper and two atoms by weight of zinc ($3Cu + 2Zn$). The hardness of the alloy is the same as that of fluor spar; it can be scratched by apatite (phosphate of lime), consequently its hardness is $= 4$. The alloy is harder than copper, very tough, and is, in a properly managed fire, malleable; so much so that a key was forged out of a cast rod.

These important properties of this alloy warrant an expectation of its application to many purposes in the arts, and it would appear that they depend on its definite chemical proportions.

We learn some further particulars from the "Gewerbeverein," of Lower Austria. The commission obtained from an English specimen 65·03 of copper and 34·76 zinc. Elsner analysed a malleable brass, and found it to contain 61·16 copper and 39·71 zinc. These numbers approximate to the composition Cu^2Zn^2 (59·4 per cent. copper and 40·6 zinc).—*Liebig and Kopp's Report.*

The alloy noticed in the preceding paragraphs, is identical with that known as "Muntz's patent sheathing"; (see table on opposite page).

The chief properties of value in brass, are its colour, hardness (which is superior to that of copper), and power of taking delicate impressions when cast in a mould. As a rule, the malleability diminishes with the increase in the quantity of zinc.

Influence of impurities on brass.—The effect of the admixture of foreign metals on brass is somewhat similar to that produced by them in copper. Antimony is most injurious, as it renders the metal brittle and liable to crack at the edges in rolling.

Lead also has a hardening effect on brass, and is useful for all work that requires to be turned or filed; as the addition of about two per cent. causes the turnings to break short, and thus prevents the tool from becoming clogged. The same effect is produced in brass for engraving by the addition of a small quantity of tin.

The surface of brass work requires to be protected from the action of the air, by a coating of a less oxidizable metal, or a resinous varnish or lacquer. The metal is first brought up to a clean face by the process of "dipping" or immersion into weak nitric acid, whereby the adherent scale or oxide formed during annealing is removed. By varying the strength of the acid employed, and repeating the dipping, the metal may be made to assume a "matt," dead, or frosted appearance. After dipping, the metal is washed in water, and dried by imbedding it in hot sawdust. The lacquer, which is an alcoholic solution of shellac, more or less coloured with dragon's blood, according to the tint desired in the finished work, is brushed over the article when in a heated state, and dried over a stove. The colour in the lacquer helps to produce a higher or more golden tint than that due to the metal alone.

Brass work is bronzed in several different ways; the most usual are, immersion in a solution of arsenious acid, in hydrochloric acid, or in bichloride of platinum. The former is chiefly employed for cheap work, such as common gas fittings, while the latter is used for blacking or bronzing telescopes, mathematical instruments, and similar fine work. The effect, in either case, is the production of a film of dark coloured metal on the surface of the brass, namely, arsenic in the former, and platinum in the latter case. This operation is performed after dipping, and before lacquering.

For the method of covering brass with a film of tin, see PIN MANUFACTURE.

BRASS FOIL. Dutch leaf, called *Knitter* or *Rauschgold* in Germany, is made from a very thin sheet brass, beat out under a hammer worked by water power, which gives from 300 to 400 strokes per minute, from 40 to 80 leaves being laid over each

Digitized by Google

other. By this treatment it may be reduced to leaves not more than $\frac{1}{50,000}$ of an inch thick. The metal employed is one rich in copper.

Brass, Yellow. The following Table exhibits the composition of several varieties of this species of brass. No. 1 is a cast brass of uncertain origin; 2, the brass of Jemappes; 3, the sheet brass of Stolberg, near Aix-la-Chapelle; 4 and 5, the brass for gilding, according to D'Arcet; 6, the sheet brass of Romilly; 7, English brass wire; 8, Augsburg brass wire; 9, brass wire of Neustadt-Eberswald, in the neighbourhood of Berlin:—

Tombak, or Red Brass, in the cast state, is an alloy of copper and zinc, containing not more than 20 per cent. of the latter constituent. The following varieties are distinguished:—1, 2, 3, tombak for making gilt articles; 4, French tombak for sword-handles, &c.; 5, tombak of the Okar, near Goslar, in the Hartz; 6, yellow tombak of Paris for gilt ornaments; 7, tombak for the same purpose from a factory in Hanover; 8, chrysochalk; 9, red tombak from Paris; 10, red tombak of Vienna.

Mr. Holtzapffel, in his "Mechanical Manipulation," has given some very important descriptions of alloys. From his long experience in manufacture, no one was more capable than Mr. Holtzapffel to speak with authority on the alloys of copper and zinc. From his work, the following particulars have been obtained:—

The red colour of copper slides into that of yellow brass at about 4 or 5 ounces of zinc to the pound of copper, and remains little altered unto about 8 or 10 ounces; after this it becomes whiter, and when 32 ounces of zinc are added to 16 of copper, the mixture has the brilliant silvery colour of speculum metal, but with a bluish tint.

These alloys—from about 8 to 16 ounces to the pound of copper—are extensively used for dipping, a process adopted for giving a fine colour to an enormous variety of furniture work. The alloys with zinc retain their malleability and ductility well unto about 8 or 10 ounces to the pound; after this the crystalline character slowly begins to prevail. The alloy of 2 zinc and 1 copper may be crumbled in a mortar when cold. In the following list, the quantity of zinc employed to 1 lb. of copper is given:—

1 to 1¼ oz. gilding metal for common jewellery.
3 to 4 oz. Bath metal, pinchbeck, Mannheim gold, Similor; and alloys bearing various names, and resembling inferior jewellers' gold.
8 oz. Emerson's patent brass.
10¾ oz. Muntz's metal, or 40 zinc and 60 copper. "Any proportions," says the patentee, "between the extremes, 50 zinc and 50 copper and 37 zinc and 63 copper, will roll and work well at a red heat."
16 oz. soft spelter solder, suitable for ordinary brass work.
16¼ oz. Hamilton and Parker's patent mosaic gold.

Brass is extensively employed for the bearings of machinery. Several patents have been taken out for compositions varying but slightly. The following, for improvements in casting the bearings and brasses of machinery, appears important:—Mr. W. Hewit-

Digitized by Google

son, of Leeds, directs, in his patent, that the proper mixture of alloy, copper, tin, and zinc, should be run into metal or "chill" moulds, in place of the ordinary moulds. In large castings, it is found more especially that the metals do not mix intimately in cooling, or, rather, they arrange themselves into groups when cast in sand, and the bearings are found to wear out more quickly; but if the bearings are cast so that the alloy comes in contact with metal, the mixture is more intimate, and the bearings last longer than if cast in dry or green sand moulds.

Mr. Hewitson generally only applies these chill-metal surfaces of the moulds to those parts of a brass, or bearing, that are to receive the shaft or bear the axis of a machine. The chills are preferred of iron, perforated with holes ($\frac{1}{16}$th to $\frac{1}{8}$th inch) for the passage of air or vapours; the surface should be thinly coated with loam, and heated to about 200°.

Fenton's patent metal consists of copper, spelter, and tin: it has less specific gravity than gun metal, and is described as being "of a more soapy nature," by which, consequently, the consumption of oil or grease is lessened.

Many of the patentees of bearing metals assure us, that the metals they now use differ very considerably from the statement in their specifications. Surely this requires a careful examination.

We *exported* of our BRASS MANUFACTURES, in 1864, as follows:—

	Cwts.	£
Brass wire of all sorts, and manufactures of wire -	10,950	54,648
Brass tubing - - - - - - - - -	8,077	41,554
Wrought brass of all other sorts, not being ordnance and not otherwise described - -	23,646	137,811

In the same year we *imported*:—

Brass manufactures, unenumerated - - - -	4,643	49,802
Brass, old, fit only to be remanufactured - - -	3,085	6,325

BRASS COLOUR, for staining glass, is prepared by exposing for several days thin plates of brass upon tiles in the *leer*, or annealing arch of the glass house, till they are oxidised into a black powder, aggregated in lumps. This being pulverised and sifted, is to be again well calcined for several days more, till no particles remain in the metallic state, when it will form a fine powder of a russet-brown colour. A third calcination must now be given with a carefully regulated heat, its quality being tested from time to time by fusion with some glass. If it makes the glass swell and intumesce, it is properly prepared; if not, it must be still further calcined. Such a powder communicates to glass greens of various tints, passing into turquoise.

When thin narrow strips of brass are stratified with sulphur in a crucible, and calcined at a red heat, they become friable and may be reduced to powder. This being sifted and exposed upon tiles in a reverberatory furnace for 10 or 12 days, becomes fit for use, and is capable of imparting a chalcedony—red or yellow—tinge to glass by fusion, according to the mode and proportion of using it.

The glassmakers' red colour may be prepared by exposing small plates of brass to a moderate heat in a reverberatory furnace till they are thoroughly calcined, when the substance becomes pulverulent, and assumes a red colour. It is then ready for immediate use.

Brass colour, as employed by the colourmen to imitate brass, is of two tints—the red or bronze, and the yellow, like gilt brass. Copper filings mixed with red ochre, or bole, constitute the former; a powdered brass, imported from Germany, is used for the latter. Both must be worked up with varnish after being dried with heat, and then spread flat with a camel-hair brush evenly upon the surface of the object. The best varnish is composed of 20 ounces of spirits of wine, 2 ounces of shellac, and 2 ounces of sandarach, properly dissolved. (See VARNISH.) Only so much of the brass powder and varnish should be mixed at a time as is wanted for immediate use. See BRONZE POWDER.

BRASSES COAL, or BRASS OF COAL. Names given to iron pyrites found in the coal measures. In 1864, it was estimated that the following quantities were produced and used:—

NORTHUMBERLAND and DURHAM - - -	7,560 tons.
YORKSHIRE - - - - - - - -	3,425 „
LANCASHIRE - - - - - - - -	2,500 „

These sulphur ores are employed in Yorkshire, Lancashire, and on the Tyne, in the manufacture of the protosulphate of iron (copperas.) For this purpose they are extended in wide-spread heaps, and thus exposed to atmospheric influences. The

Digitized by Google

result is the conversion of the sulphur into sulphuric acid, which reuniting with the iron forms the sulphate of the protoxide of iron, which is dissolved out and crystallised. It is the presence of iron pyrites in coal (Brasses), which gives the tendency to spontaneous combustion. A large number of the ships which are sent from South Wales to Chili, with coals, which are used for smelting the copper ores of that country, take fire when they reach the tropics. This arises mainly from carelessness. In the first place, the coals are not carefully selected. They are bought cheaply, and being small, are put on board the ships, without being washed or picked, and frequently damp. During the voyage, decomposition goes on, and by the time they reach the warmer latitudes, a temperature sufficiently high to occasion actual combustion is produced. By carefully washing the coal and drying it, these casualties might be almost entirely prevented. BRASS is a name given to an iron ore found in the coal measures of South Wales, which is not a pyritic ore, although for a long period mistaken for it. See COAL BRASS.

BRASSING IRON. Iron ornaments are covered with copper or brass by properly preparing the surface, so as to remove all organic matter, which would prevent adhesion, and then plunging them into melted brass. A thin coating is thus spread over the iron, and it admits of being polished or burnished. The electro-magnetic process is now employed for the purpose of precipitating brass on iron. This process was first mentioned in Shaw's "Metallurgy," in 1844, where he remarks, "In depositing copper upon iron, a solution of the cyanide or acetate of copper should be employed. The only value of these salts is, that a dye or surface of iron may be immersed in their solutions without receiving injury by the corrosion consequent upon the deposition of a film of metal by chemical action." The following solutions are recommended by Dr. Woods, in the "Scientific American," for coating iron with copper, zinc, or brass, by the electrotype process.

To make a *Solution of Copper or Zinc.*—Dissolve 8 ounces (troy) cyanide of potassium and 3 ounces of cyanide of copper or zinc in 1 gallon of rain or distilled water. These solutions to be used at about 160° F. with a compound battery of from 3 to 12 cells.

To prepare a *Solution of Brass.*—Dissolve 1 lb. (troy) cyanide of potassium, 2 ounces of cyanide of copper, and 1 ounce of cyanide of zinc, in one gallon of rain or distilled water; then add two ounces of muriate of ammonia. This solution is to be used at 160° F. for smooth work, and from 90° to 120°, with a compound battery of from 3 to 12 cells. See ELECTRO-METALLURGY.

BRATTICE. The division in a shaft of a colliery is so called. It is used to ensure an up and a down cast current. Brattices may be also used in any of the levels for the same purpose. They may be of metal, of wood, or tarred canvas. Mining engineers speak of a *natural brattice*, i. e. one independent of any artificial arrangement—when the currents separate naturally in a shaft or a level—and thus produce a natural ventilation.

BRAZILIAN ARROW ROOT. See ARROW ROOT.

BRAZIL NUTS. The hard-shelled fruit of the *Bertholletia Excelsa*, which is roundish and about six inches in diameter, contains about two dozen of the elongated wrinkled triangular seeds—these are the "nuts" of the shops. See PARA NUTS.

BRAZIL WOOD. (*Bois de Pernambouc*, Fr.; *Brasilienholz*, Germ.) This dye-wood gives its name to the part of America whence it was first imported. It has also the names of Pernambuca, wood of St. Martha, and of Sapan, according to the places which produce it. Linnæus distinguishes the tree which furnishes the Brazil wood by the name of *Cæsalpinia crista*. It commonly grows in dry places among rocks. Its trunk is very large, crooked, and full of knots. It is very hard, susceptible of a fine polish, and sinks in water. It is pale when newly cleft, but becomes red on exposure to the air. The following is a very exact description of the tree producing this wood:—

The *ibiripitanga*, or Brazil wood, called, in Pernambuco, *pao da rainha* (Queen's wood), on account of its being a Government monopoly, is now rarely to be seen within many leagues of the coast, owing to the improvident manner in which it has been cut down by the Government agents, without any regard being paid to the size of the tree or its cultivation. It is not a lofty tree. At a short distance from the ground, innumerable branches spring forth and extend in every direction in a straggling, irregular, and unpleasing manner. The leaves are small and not luxuriant; the wood is very hard and heavy, takes a high polish, and sinks in water; the only valuable portion of it is the heart, as the outward coat of wood has not any peculiarity. The name of this wood is derived from *brasas*, a glowing fire or coal; its botanical name is *Cæsalpinia Brasileto*. The leaves are pinnated, the flower white and papilionaceous, growing in a pyramidal spike: one species has flowers variegated with red. The

Digitized by Google

branches are slender and full of small prickles. There are nine species. See Bell's "Geography."

The species *Brasileto*, which is inferior to the *crista*, grows in great abundance in the West Indies. The demand for the *Brasileto*, a few years ago, was so great, owing to its being a little cheaper than the *crista*, that nearly the whole trees in the British possessions were cut down and sent home, which Mr. Bell very justly terms improvidence. It is not now so much used, and is consequently scarcer in the English market.

The wood known in commerce as *Pernambuco* is most esteemed, and has the greatest quantity of colouring matter. It is hard, has a yellow colour when newly cut, but turns red by exposure to the air. That kind termed *Lima wood* is the same in quality. *Sapan wood* grows in Japan, and in quality is next the two named above. It is not plentiful, but is much valued in the dyehouse for red of a certain tint; it gives a very clear and superior colour. The quantity of ash that these two qualities of wood contain is worthy of remark. Lima wood, as imported, gives the average of 2·7 per cent., while Sapan wood gives 1·5 per cent.; in both, the prevailing earth is lime. The quantity of moisture in the wood averages about 10 per cent.; that in the ground wood in the market about 20 per cent.

Brazil wood has different shades of red and orange. Its goodness is determined particularly by its density. When chewed, a saccharine taste is perceived. It may be distinguished from red saunders wood by its colouring water, which the latter does not.

BRAZIL WOOD DYES. Boiling water extracts the whole colouring matter of Brazil wood, and if the ebullition be long enough continued, it assumes a fine red colour. The residuum appears black. In this case an alkali may still extract much colouring matter. The solution in alcohol or ammonia is still deeper than the preceding.

The decoction of Brazil wood, called juice of Brazil, is observed to be less fit for dyeing when recent than when old, or even fermented. By age it takes a yellowish-red colour. For making this decoction, Hellot recommends the use of the hardest water; but it should be remarked that this water deepens the colour in proportion to the *earthy* salts which it contains. After boiling this wood reduced to chips, or, what is preferable, to powder, for three hours, this first decoction is poured into a cask. Fresh water is poured on the wood, which is then made to boil for three hours, and mixed with the former. When Brazil wood is employed in a dyeing bath, it is proper to inclose it in a thin linen bag.

Wool immersed in the juice of Brazil wood takes but a feeble tint, which is speedily destroyed; it must therefore receive some preliminary preparations.

The wool is to be boiled in a solution of alum, to which a fourth or even less of tartar is added, for a larger proportion of tartar would make the colour yellowish. The wool is kept impregnated with it, for at least eight days, in a cool place. After this, it is dyed in the Brazil juice with a slight boiling. But the first colouring particles that are deposited afford a less beautiful colour; hence it is proper to pass a coarser stuff previously through the bath. In this manner a lively red is procured, which resists pretty well the action of the air.

Brazil wood is made use of for dyeing silk the colour known as false crimson, to distinguish it from the crimson made by means of cochineal, which is much more permanent.

The silk should be boiled at the rate of 20 parts of soap per cent., and then alumed. The aluming need not be so strong as for the fine crimson. The silk is refreshed at the river, and passed through a bath more or less charged with Brazil juice, according to the shade to be given. When water free from earthy salts is employed, the colour is too red to imitate crimson; this quality is given it by passing the silk through a slight alkaline solution, or by adding a little alkali to the bath. It might, indeed, be washed in a hard water till it had taken the desired shade. They thus become permament colours. But what distinguishes them from madder and kermes, and approximates them to cochineal, is their reappearing in their natural colour, when they are thrown down in a state of combination with alumina, or with oxide of tin. These two combinations seem to be the fittest for rendering them durable. It is requisite, therefore, to inquire what circumstances are best calculated to promote the formation of these combinations according to the nature of the stuff.

The astringent principle, likewise, seems to contribute to the permanence of the colouring matter of Brazil wood; but it deepens its hue, and can only be employed for light shades.

To make deeper false crimsons, a dark red juice of logwood is put into the Brazil bath after the silk has been impregnated with it. A little alkali may be added, according to the shade that is wanted.

To imitate poppy or flame colour, an arnotto ground is given to the silk, deeper

Digitized by Google

even than when it is dyed with carthamus; it is then washed, alumed, and dyed with juice of Brazil, to which a little soap water is usually added.

The colouring particles of Brazil wood are easily affected, and made yellow by the action of acids.

The colouring particles of Brazil wood are very sensible to the action of alkalis, which give them a purple hue; and there are several processes in which the alkalis, either fixed or volatile, are used for forming violets and purples. But the colours obtained by these methods, which may be easily varied according to the purpose, are perishable, and possess but a transient bloom. The alkalis appear not to injure the colours derived from madder, but they accelerate the destruction of most other colours.

In England and Holland the dye-woods are reduced to powder by means of mills erected for the purpose.

The bright fugitive red, called fancy red, is given to cotton by Nicaragua, or peach wood, a cheap kind of Brazil wood. See PEACH WOOD.

The cotton being scoured and bleached, is boiled with sumach. It is then impregnated with a solution of tin (at 5° B., according to Vitalis). It should now be washed slightly in a weak bath of the dyeing wood; and, lastly, worked in a somewhat stale infusion of the peach or Brazil wood. When the temperature of this is lukewarm, the dye is said to take better. Sometimes two successive immersions in the bath are given. It is now wrung out, aired, washed in water, and dried.

M. Vitalis says, that his solution of tin is prepared with two ounces of tin and a pound of aqua regia, made with two parts of nitric acid at 24° B. and three parts of muriatic acid at 22°.

For a rose colour, the cotton is alumed as usual, and washed from the alum. It then gets the tin mordant, and is again washed. It is now turned through the dye-bath, an operation which is repeated if necessary.

For purple, a little alum is added to the Brazil bath.

1. For amaranth, the cotton is strongly galled, dried, and washed.
2. It is passed through the black cask (*tonneau noir*, see BLACK DYE), till it has taken a strong grey shade.
3. It receives a bath of lime water.
4. Mordant of tin.
5. Dyeing in the Brazil wood bath.
6. The last two operations are repeated.

Dingler has endeavoured to separate the colouring matter of the different sorts of Brazil wood, so as to obtain the same tint from the coarser as from the best Pernambuco. His process consists in treating the wood with hot water or steam, in concentrating the decoction so as to obtain 14 or 15 pounds of it from 4 pounds of wood, allowing it to cool, and pouring into it two pounds of skim milk; agitating, then boiling for a few minutes, and filtering. The dun colouring matters are precipitated by the coagulation of the caseous substance. For dyeing, the decoctions must be diluted with water; for printing, they must be concentrated so that 4 pounds of wood shall furnish only 5 or 6 pounds of decoction, and the liquor may be thickened in the ordinary way. These decoctions may be employed immediately, as by this treatment they have acquired the same property as they otherwise could get only by being long kept. A slight fermentation is said to improve the colour of these decoctions; some ground wood is put into the decoction to favour this process.

Gall-nuts, however, sumach, the bark of birch or alder, render the colour of Brazil wood more durable upon alumed linen and cotton goods, but the shade is a little darker.

In dyeing wool with Pernambuco Brazil wood, the temperature of the bath should never be above 150° F., since higher heats impair the colour.

According to Dingler and Kurrer, bright and fast scarlet reds may be obtained upon wool, by preparing a decoction of 50 pounds of Brazil wood in three successive boils, and setting the decoction aside for 3 or 4 weeks in a cool place; 100 pounds of the wool are then alumed in a bath of 22 pounds of alum and 11 pounds of tartar, and afterwards rinsed in cold water. Meanwhile we fill two-thirds with water a copper containing 30 pails, and heated to the temperature of 150° or 160° F. We pour in 3 pailfuls of the decoction, heat to the same point again, and introduce 30 pounds of wool, which does not take a scarlet, but rather a crimson tint. This being removed, 2 pails of decoction are put in, and 30 pounds of wool, which becomes scarlet, but not so fine as at the third dip. If the dyer strengthens the colour a little at the first dip, a little more at the second, and adds at the third and fourth the quantity of decoction merely necessary, he will obtain an uniform scarlet tint. With 50 pounds of Pernambuco, 1000 pounds of wool may be dyed scarlet in this way, and with the deposits another 100 may be dyed of a tile colour. An addition of weld renders the colour faster, but less brilliant. See WELD.

Karkutsch says the dye may be improved by adding some ox-gall to the bath.

In dyeing cotton, the tannin and gallic acid are two necessary mordants, and the colour is particularly bright and durable when the cloth has been prepared with the oily process of Turkey red.

It is said that stale urine heightens the colour of the Brazil dye when the ground wood is moistened with it.

Chevreul obtained the colouring matter from Brazil wood in the following manner: — Digest the raspings of the wood in water till all the colouring matter is dissolved, and evaporate the infusion to dryness, to get rid of a little acetic acid which it contains. Dissolve the residue in water, and agitate the solution with litharge, to get rid of a little fixed acid. Evaporate again to dryness; digest the residue in alcohol; filter and evaporate, to drive off the alcohol. Dilute the residual matter with water, and add to the liquid a solution of glue, till all the tannin which it contains is thrown down; filter again, and evaporate to dryness, and digest the residue in alcohol, which will leave undissolved any excess of glue which may have been added. The last alcoholic solution, being evaporated to dryness, leaves *brezilin*, the colouring matter of the wood, in a state of considerable purity.

The *importations* of BRAZIL WOOD (which has been admitted free since 19th March, 1845) in 1864 were as follows:—

	Tons.	Computed real value.
From United States: Ports on the Pacific	750	£7,500
Mexico	930	9,300
Central America	306	3,060
Other parts	84	840
	2,070	20,700

BRAZILIN and BRAZILEIN are two colouring matters which have been separated from Brazil wood, by Chevreul and Preisser. They are probably identical. See Watts' "Dictionary of Chemistry."

BRAZING. See SOLDERS and SOLDERING.

BREAD. One of the most important, if not altogether the most important, article of food, unquestionably, is bread; and although rye, barley, oats, and other cereals, are sometimes used by the baker, *wheat* is the grain which is best fitted for the manufacture of that article, not only on account of the larger amount of gluten, or nitrogenous matter, which it contains, and than can be found in other edible grains, but also on account of the almost exact balance in which the nitrogenous and non-nitrogenous constituents exist in that cereal, and owing to which it is capable of ministering to all the requirements of the human frame, and of being assimilated at once and without effort by our organs, whence the name of "staff of life," which is often given to it, wheat being, like milk, a perfect food.

Although gluten is one of the most important constituents of wheat, the nutritive power of its flour, and its value as a bread-making material, should not be altogether considered as dependent upon the quantity of gluten it may contain, even though it be of the best quality. Doubtless a high per-centage of this material is desirable, but there are other considerations which must be taken into account; for, in order to become available for making good bread, flour, in addition to being sound and genuine, must possess other qualities beyond containing merely a large amount of gluten. Thus, for example, the *blé rouge glacé d'Auvergne*, which contains hardly 45 per cent. of starch, and as much as 36 per cent. of gluten, though admirably adapted for the manufacture of macaroni, vermicelli, semolina, and other *pâtes d'Italie*, is totally unfit for making good bread; the flour used for making best white loaves containing only from 10 to 18 per cent. of gluten, and from 60 to 70 per cent. of starch.

Bread is obtained by baking a dough, previously fermented either by an admixture of yeast or leaven, or it is artificially rendered spongy by causing an acid, muriatic or tartaric, to react upon carbonate or bicarbonate of soda, or of ammonia, mixed in the doughy mass; or, as in Dr. Dauglish's process, which will be described further on, by mixing the flour which has to be converted into dough, not with ordinary water, but with water strongly impregnated with carbonic acid.

Although a history of bread making cannot be introduced in the present article, a few words on the subject, reproduced from the former edition of this work, will not be deemed uninteresting.

Pliny informs us, that barley was the only species of corn at first used for food; and even after the method of reducing it to flour had been discovered, it was long before mankind learned the art of converting it into cakes.

Ovens were first invented in the East. Their construction was understood by the Jews, the Greeks, and the Asiatics, among whom baking was practised as a distinct

Digitized by Google

profession. In this art, the Cappadocians, Lydians, and Phœnicians, are said to have particularly excelled. It was not till about 580 years after the foundation of Rome that these artisans passed into Europe. The Roman armies, on their return from Macedonia, brought Grecian bakers with them into Italy. As these bakers had handmills beside their ovens, they still continued to be called *pistores*, from the ancient practice of bruising the corn in a mortar; and their bakehouses were denominated *pistoriæ*. In the time of Augustus there were no fewer than 329 public bakehouses in Rome; almost the whole of which were in the hands of Greeks, who long continued the only persons in that city acquainted with the art of baking good bread.

In nothing, perhaps, is the wise and cautious policy of the Roman government more remarkably displayed, than in the regulations which it imposed on the bakers within the city. To the foreign bakers who came to Rome with the army from Macedonia, a number of freedmen were associated, forming together an incorporation from which neither they nor their children could separate, and of which even those who married the daughters of bakers were obliged to become members. To this incorporation were entrusted all the mills, utensils, slaves, animals, everything, in short, which belonged to the former bakehouses. In addition to these, they received considerable portions of land; and nothing was withheld which could assist them in pursuing, to the best advantage, their highly prized labours and trade. The practice of condemning criminals and slaves, for petty offences, to work in the bakehouse, was still continued; and even the judges of Africa were bound to send thither, every five years, such persons as had incurred that kind of chastisement. The bakehouses were distributed throughout the fourteen divisions of the city, and no baker could pass from one into another without special permission. The public granaries were committed to their care; they paid nothing for the corn employed in baking bread that was to be given in largess to the citizens; and the price of the rest was regulated by the magistrates. No corn was given out of these granaries except for the bakehouses, and for the private use of the prince. The bakers had besides private granaries, in which they deposited the grain which they had taken from the public granaries for immediate use; and if any of them happened to be convicted of having diverted any portion of the grain to another purpose, he was condemned to a ruinous fine of five hundred pounds' weight of gold.

Most of these regulations were soon introduced among the Gauls; but it was long before they found their way into the more northern countries of Europe. Borrichius informs us that in Sweden and Norway, the only bread known, so late as the middle of the 16th century, was unleaven cakes kneaded by the women. At what period in our own history the art of baking became a separate profession, we have not been able to ascertain; but this profession is now common to all the countries in Europe, and the process of baking is also nearly the same.

The French, who particularly excel in the art of baking, have a great many different kinds of bread. Their *pain bis*, or brown bread, is the coarsest kind of all, and is made of coarse groats mixed with a portion of white flour. The *pain de méteil* is a bread made with rye and barley flour, to which wheat flour is sometimes added also. The *pain bis blanc*, is a kind of bread between white and brown, made of white flour and fine groats. The *pain blanc*, or white bread, is made of white flour, shaken through a sieve after the finest flour has been separated. The *pain mollet*, or soft bread, is made of the purest flour without any admixture. The *pain chaland*, or customers' bread, is a very white kind of bread, made of pounded paste. *Pain chapelé*, is a small kind of bread, with a well-beaten and very light paste, seasoned with butter or milk. This name is also given to a small bread, from which the thickest crust has been removed by a rasp. *Pain cornu* is a name given by the French bakers to a kind of bread made with four corners, and sometimes more. Of all the kinds of small bread this has the strongest and firmest paste. *Pain à la reine*, queen's bread, *pain à la Ségovie*, *pain chapelé*, and *pain cornu*, are all small kinds of bread, differing only in the lightness or thickness of the paste. *Pain de gruau* is a small very white bread made now in Paris, from the flour separated after a slight grinding from the best wheat. Such flour is in hard granular particles.

In England, however, we have but few varieties of bread, the loaves known under the names of *bricks*, *Coburg*, *cottage*, *batch*, and *French rolls*, being all made of the same dough; the only difference is in the *shape* given to them, their various flavours depending on the way in which they are affected by the heat of the oven in the baking. These loaves are crusted all over because they are deposited in the oven separate from each other, or baked in moulds made of tinned iron, whereas the batch bread is crusted only at the top and bottom, because the loaves, which have a cubic form, touch each other in the oven; those, however, which lie round the oven have a crust on three of their sides. The cottage and French rolls are *generally* made of best flour,—known under the name of whites;—but batch bread is made of best flour

Digitized by Google

and of households, or flour of second quality, and of *seconds*, which is flour of a third quality — that is, of flour containing more bran than the other kinds just enumerated.

We have also "rye bread," which is generally made of nothing else than ordinary wheat flour and bran.

Dr. Ure, in the former edition of this Dictionary, truly remarked, "The object of baking is to combine the gluten and starch of the flour into a homogeneous substance, and to excite such a vinous fermentative action, by means of its saccharine matter, as shall disengage abundance of carbonic acid gas in it for making an agreeable, soft, succulent, spongy, and easily digestible bread. The two evils to be avoided in baking are, hardness on the one hand and pastiness on the other. Well-made bread is a chemical compound, in which the gluten and starch cannot be recognised or separated, as before, by a stream of water. When flour is kneaded into a dough, and spread into a cake, this cake, when baked, will be horny if it be thin, or if thick, will be tough and clammy; whence we see the value of that fermentative process, which generates thousands of little cells in the mass or crumb, each of them dry yet tender and succulent through the intimate combination of the moisture. By this constitution it becomes easily soluble in the juices of the stomach, or, in other words, light of digestion. It is moreover much less liable to turn sour than cakes made from unfermented dough.

"Rye, which also forms a true spongy bread, though inferior to that of wheat, consists of similar ingredients — namely, 61·07 of starch, 9·48 of gluten, 3·28 of vegetable albumen, 3·23 of uncrystallisable sugar, 11·09 of gum, 6·38 of vegetable fibre; the loss upon the 100 parts amounted to 5·62, including an acid whose nature the analyst, M. Einhof, did not determine. Rye flour contains also several salts, principally the phosphates of lime and magnesia. This kind of grain forms a dark-coloured bread, reckoned very wholesome; comparatively little used in this country, but very much in France, Germany, and Belgium.

"Dough, fermented with the aid either of leaven or yeast, contains little or none of the saccharine matter of the flour, but, in its stead, a certain portion, nearly half its weight, of spirit, which imparts to it a vinous smell, and is volatilised in the oven, whence it might be condensed into a crude, weak alcohol, on the plan of Mr. Hick's patent, were it worth while. But the increased complexity of the baking apparatus will probably prove an effectual obstacle to the commercial success of this project, upon which a few years ago upwards of 20,000*l.* sterling were foolishly squandered.

"That the sugar of the flour is the true element of the fermentation which dough undergoes, and that the starch and gluten have nothing to do with it, may be proved by decisive experiments. The vinous fermentation continues till the whole sugar is decomposed, and no longer; when, if the process be not checked by the heat of baking, the acetous fermentation will supervene. Therefore, if a little sugar be added to a flour which contains little or none, its dough will become susceptible of fermenting, with extrication of gas, so as to make spongy succulent bread. But since this sponginess is produced solely by the extrication of gas and its expansion in the heat of the oven, any substance capable of emitting gas, or of being converted into it under these circumstances, will answer the same purpose. Were a solution of bicarbonate of ammonia obtained by exposing the common sesquicarbonate in powder for a day to the air, incorporated with the dough, in the subsequent firing it will be converted into vapour, and, in its extrication, render the bread very porous. Nay, if water highly impregnated with carbonic acid gas be used for kneading the dough, the resulting bread will be somewhat spongy. Could a light article of food be prepared in this way, then, as the sugar would remain undecomposed, the bread would be so much the sweeter and the more nourishing. How far a change propitious to digestion takes place in the constitution of the starch and gluten during the fermentative action of the dough has not been hitherto ascertained by precise experiments.

"Dr. Colquhoun, in his able essay upon the art of making bread, has shown that its texture, when prepared by a sudden formation and disengagement of elastic fluid generated within the oven, differs remarkably from that of a loaf which has been made after the preparatory fermentation with yeast. Bread which has been raised with the common carbonate of ammonia, as used by the pastry-cooks, is porous no doubt, but not spongy with vesicular spaces, like that made in the ordinary way. The former kind of bread never presents that air-cell stratification which is the boast of the Parisian baker, but which is almost unknown in London. It is, moreover, very difficult to expel by the oven the last portion of the ammonia, which gives both a tinge and a taste to the bread. The bicarbonate would probably be free from this objection, which operates so much against the use of the sesquicarbonate."—*Ure.*

The conversion of flour into bread includes two distinct operations — namely, the preparation of the dough and the baking. The preparation of the dough, however

Digitized by Google

though reckoned as one, consists, in fact, of three operations — namely, *hydrating*, *kneading*, and *fermenting*.

When the baker intends to make a batch of bread, his first care is, in technical language, *to stir a ferment*. This is done, in London, by boiling a few potatoes, in the proportion of 5 lbs. or 6 lbs. of potatoes per sack of flour (which is the quantity we shall assume it is desired to convert into bread), peeling them, mashing and straining them through a cullender, and adding thereto about three-quarters of a pailful of water, 2 or 3 lbs. of flour, and one quart of yeast. The water employed need not be warmed beforehand, for the heat of the potatoes is sufficient to impart a proper temperature (from 70° to 90° F.) to the liquid mass, which should be well stirred up with the hand into a smooth, thin, and homogeneous paste, and then left at rest.

In the course of an hour or two, the mass is seen to rise and fall, which swelling and heaving up is due to carbonic acid, generated by the fermentation induced in the mass, which may be thus left until wanted. In about three hours, this fermenting action will appear to be at an end, and when it has arrived at that stage, it is fit to be used. The ferment, however, may be left for six or seven hours and be still very good at the end of that time, but the common practice is to use it within four or five hours after its preparation.

The next operation consists in "*setting the sponge*." This consists in stirring the ferment well, adding thereto about two gallons of lukewarm water, and as much flour as will make, with the ferment, a rather stiff dough. This constitutes "*the sponge*." It is kept in a warm situation, and in the course of about an hour fermentation again begins to make its appearance, the mass becomes distended or is heaved up by the carbonic acid produced, the escape of which is impeded by the toughness of the mass. This carbonic acid is the result of the fermentation induced under the influence of water, by the action of the gluten upon the starch, a portion of which is converted thereby into sugar, and then into alcohol. A time, however, soon comes when the quantity of carbonic acid thus pent up becomes so great that it bursts through, and the sponge collapses or drops down. This is called the *first sponge*.—But as the fermentation is still going on, the carbonic acid soon causes the sponge to rise again as before to nearly twice its volume, when the carbonic acid, bursting through the mass, causes it to fall a second time; and this constitutes what the bakers call the *second sponge*. The rising and falling might then go on for twenty-four hours; but as the alcoholic would pass into the acetous fermentation soon after the second rising, the baker always interferes after the second, and very frequently after the first sponge. The bread made from the first sponge is generally sweeter; but unless the best flour is used, and even then, the loaf that is made from it is smaller in size and more compact than that which is made with the *second sponge*. In hot weather, however, as there would be much danger of the bread turning sour, if the sponge were allowed to "*take a second full*," the first sponge is frequently used. The next process consists in *breaking the sponge*, which is done by adding to it the necessary quantity of water and of salt,—the quantity of the latter substance varying from ½ lb. to ¾ of a pound per bushel of flour; that is, from 2½ lbs. to 3¾ lbs. per sack of flour (new flour, or flour of inferior quality, always requires, at the very least, 3½ lbs. per sack, *to bind it*, that is to say, to render the dough sufficiently firm to support itself while fermenting). Salt acts, to a great extent, like alum, though not so powerfully. As to the quantity of water to be used, it depends also a great deal on the quality of the flour, the best quality absorbing most; though, as we shall have occasion to remark, the baker too often contrives to force and keep into bread made from inferior flour, by a process called *under baking*, the same amount of water as is normally taken up by that of the best quality. Generally speaking, and with flour of good average quality, the amount of water is such, that the diluted sponge forms about 14 gallons of liquid. The whole mass is then torn to pieces by the hand, so as to break any lumps that there may be, and mix it up thoroughly with the water. This being done, the rest of the sack of flour is gradually added and kneaded into a dough of the proper consistency. This kneading of the dough may be said to be one of the most important processes of the manufacture, since it not only produces a more complete hydration of the flour, but, by imprisoning a certain quantity of air within the dough, and forcibly bringing into closer contact the molecules of the yeast or leaven with the sugar of the flour, and also with a portion of the starch, the fermentation or rising of the whole mass, on which the sponginess of the loaf and its digestibility subsequently depend, is secured. When by forcing the hand into the dough, the baker sees that, on withdrawing it, none of the dough adheres to it, he knows that the kneading is completed. The dough is then allowed to remain in the trough for about an hour and a half or two hours, if *brewers'* or *German yeast* have been employed in making the sponge;—if, on the contrary, *patent yeast* or *hop yeast* have been used, three or even four hours may be

Digitized by Google

required for the dough to rise up, or, as in technical language, *to give proof*. When the dough is sufficiently "*proofed*," it is weighed off into lumps, shaped into the proper forms of 4 lbs. 4 oz. each, and exposed for about one hour in an oven to a temperature of about 570° F., the heat gradually falling to 430 or 420° F. The yield after baking is 94 quartern (not 4-lb.) loaves, or from 90 to 92 really 4lb. loaves, as large again as they were when put into the oven in the shape of dough.

The manner in which yeast acts upon the flour—is as, yet, an unsolved mystery, or at any rate an, as yet, unsatisfactorily explained action; for the term "catalysis," which has sometimes been applied to it, explains absolutely nothing.

A yeast, or fermenting material, may be prepared in various ways; but only three kinds of yeast are used by bakers: namely, brewers' yeast, or barm,—German yeast, and patent, or hop yeast.

The most active of these ferments is the first, or brewers' yeast; it is, as is well known, a frothy, thickish material, of a brownish or drab colour, which, when recent, is in a state of slight effervescence, exhales a sour characteristic odour, and has an acid reaction.

When viewed through the microscope, it is seen to consist of small globules of various size, generally egg-shaped. They were first described by M. Desmayières.

The best, and in fact the only, brewers' yeast used in bread-making is that from the ale breweries; porter yeast is unavailable for the purpose, because it imparts to the bread a disagreeable bitter taste.

German yeast is very extensively used by bakers. It is a pasty but easily crumbled mass, of an agreeable fruity odour, and of a dingy white colour. German yeast will remain good for a few weeks, if kept in a cool place. When in good condition, it is an excellent article; but samples of it are occasionally seized on bakers' premises, of a darker colour, viscid, and emitting an offensive cheesy odour: such German yeast, being in a putrefied state, is, of course, objectionable.

The so-called "*patent yeast*" is the cheapest and at the same time the weakest of these ferments; very good bread, however, is made with it, and it is most extensively used by bakers. It is made either with or without hops: when with hops, it is called *hop yeast*, and is nothing more than a decoction of hops to which malt is added while in a scalding hot state; when the liquor has fallen to a blood heat, a certain quantity of brewers' or German yeast is thoroughly mixed with it, and the whole is left at rest. The use of the hops is intended to diminish the tendency of this solution to become acid.

Potato yeast is a kind of "*patent yeast*" in general use.

The theory of panification is not difficult of comprehension. "The flour," says Dr. Ure, "owes this valuable quality to the gluten, which it contains in greater abundance than any of the other *cerealia* (kinds of corn). This substance does not constitute, as has been heretofore imagined, the membranes of the tissue of the perisperm of the wheat; but is enclosed in cells of that tissue under the epidermic coats, even to the centre of the grain. In this respect the gluten lies in a situation analogous to that of the starch, and of most of the immediate principles of the vegetables. The other immediate principles which play a part in *panification* are particularly the starch and the sugar; and they all operate as follows:—

"The diffusion of the flour through the water *hydrates* the starch, and dissolves the sugar, the albumen, and some other soluble matters. The kneading of the dough, by completing these reactions through a more intimate union, favours also the fermentation of the sugar, by bringing its particles into close contact with those of the leaven or yeast; and the drawing out and laminating the dough softens and stratifies it, introducing at the same time oxygen to aid the fermentation. The dough, when distributed and formed into loaves, is kept some time in a gentle warmth, in the folds of the cloth, pans, &c., a circumstance propitious to the development of their volume by fermentation. The dimensions of all the lumps of dough now gradually enlarge, from the disengagement of carbonic acid in the decomposition of the sugar, which gas is imprisoned by the glutinous paste. Were these phenomena to continue too long, the dough would become too vesicular; they must, therefore, be stopped at the proper point of sponginess, by placing the loaf lumps in the oven. Though this causes a sudden expansion of the enclosed gaseous globules, it puts an end to the fermentation, and to their growth; as also evaporates a portion of the water.

"The fermentation of a small dose of sugar is, therefore, essential to true bread making; but the quantity actually fermented is so small as to be almost inappreciable. It seems probable that in well-made dough the whole carbonic acid that is generated remains in it, amounting to one-half the volume of the loaf itself at its baking temperature, or 212° F. It thence results that less than one-hundredth part of the weight of the flour is all the sugar requisite to produce well-raised bread.

"Although the rising of the dough is determined by the carbonic acid resulting from

Digitized by Google

the decomposition of the sugar, produced by the reaction of the gluten on hydrated or moist flour, considering that the quantity of sugar necessary to produce fermentation does not amount, probably, to more than one-hundredth part of the weight of the flour employed, and perhaps to even considerably less than that,—the saving and economy which is said to accrue to the consumer from the use of unfermented bread (which is bread in which the action of yeast is replaced by an artificial evolution of carbonic acid, by decomposing bicarbonate of soda with muriatic acid, as we said before) is therefore much below what it has been estimated (25 per cent.!) by some writers; and is certainly very far from compensating for the various and serious drawbacks which are peculiar to that kind of bread, one of which—and it is not the least—is its indigestibility, notwithstanding all that may have been said to the contrary.

"In a pamphlet entitled, 'Instructions for making Unfermented Bread, by a Physician,' published in 1846, the formula recommended for bread made of wheat meal is as follows:—

Wheat meal - - - -	3 lbs. avoirdupois.
Bicarbonate of soda - -	4½ drachms troy.
Hydrochloric acid - - -	5 fluid drachms and 25 minims, or drops.
Water - - - - -	30 fluid ounces.
Salt - - - - -	¾ of an ounce troy.

"Bread made in this manner," says the author, "contains nothing but flour, common salt, and water. It has an agreeable, natural taste, keeps much longer than common bread, is *much more digestible*, and much less disposed to turn acid," &c.

Liebig, in his "Letters on Chemistry," very judiciously remarks, "that the intimate mixture of the saliva with the bread, whilst masticating it, is a condition which is favourable to the rapid digestion of the starch; wherefore the porous state of the flour in fermented bread accelerates its digestion."

Now, it is a fact, which can be readily ascertained by anyone, that unfermented bread is permeated by fluids with difficulty. It will not absorb water, hence its heavy and clammy feel; nor saliva, hence its indigestibleness; nor milk, nor butter. Unfermented bread will neither make soup, nor toast, nor poultice. When a slice of ordinary bread is held before a bright fire, a portion of the moisture of the bread, as the latter becomes scorched, is converted into steam, which penetrates the interior of the mass, and imparts to it the sponginess so well known in a toast properly made; but if a piece of unfermented bread be treated in the same manner, the steam produced by the moisture, not being able to penetrate the unabsorbent mass, evaporates, and the result is an uninviting slice, toasted, but hard inside and out, and into which butter penetrates about to the same extent as it would a wooden slab of the same dimensions.

"Fermentation," says Liebig, "is not only the best and simplest, but likewise the most economical way of imparting porosity to bread: and besides, *chemists, generally speaking, should never recommend the use of chemicals for culinary preparations*, for chemicals are seldom met with in commerce in a state of purity. Thus, for example, the muriatic acid which it has been proposed to mix with carbonate of soda in bread is *always very impure*, and *very often contains arsenic*. Chemists never employ such an acid in operations which are certainly less important than the one just mentioned, without having first purified it."

In order to remove this ground of objection, tartaric acid has been recommended instead of muriatic acid for the purpose of decomposing the carbonate of soda; but in that way, another unsafe compound is introduced, since the result of the reaction is tartrate of soda, a diuretic aperient, and consequently very objectionable salt, for it is impossible to say what mischief the continuous ingestion of such a substance may eventually produce; and whatever may be the divergence of opinion,—if there be such a divergence,—as to whether or not the constant use of an aperient, however mild, may be detrimental to health, it surely must be admitted that, at any rate, it is better to eschew such, to say the least of it, suspicious materials; and that, at any rate, if deprecating their use be an error, it is an error on the safe side;—after all, a bake-house is not a chemical laboratory.

Before leaving this question of unfermented bread, we must not omit to speak of a remarkable process invented by Dr. Dauglish, and which has lately excited some attention. Without discussing the value of the idea which is said to have led Dr. Dauglish to invent the process in question, we shall simply describe Dr. Dauglish's method of making bread, and give his own version of its benefits:—

"Taking advantage of the well-known capacity of water for absorbing carbonic acid, whatever its density, in quantities equal to its own bulk, I first prepare the water which is to be used in forming the dough, by placing it in a strong vessel

Digitized by Google

capable of bearing a high pressure, and forcing carbonic acid into it to the extent of say ten or twelve atmospheres" (about 150 to 180 lbs. per square inch); "this the water absorbs without any appreciable increase in its bulk. The water so prepared will of course retain the carbonic acid in solution so long as it is retained in a close vessel under the same pressure. I therefore place the *flour and salt*, of which the dough is to be formed, also in a close vessel capable of bearing a high pressure. Within this vessel, which is of a spheroidal form, a simply-constructed kneeding apparatus is fitted, worked from without through a closely-packed stuffing box. Into this vessel I force an equal pressure to that which is maintained on the aërated water-vessel; and then, by means of a pipe connecting the two vessels, I draw the water into the flour, and set the kneading apparatus to work at the same time. By this arrangement the water acts simply as limpid water among the flour, the flour and water are mixed and kneaded together into paste, and to such an extent as shall give it the necessary *tenacity*. After this is accomplished the pressure is released, the gas escapes from the water, and in doing so raises the dough in the most beautiful and expeditious manner. It will be quite unnecessary for me to point out how perfect must be the *mechanical* structure that results from this method of raising dough. In the first place, the mixing and kneading of the flour and water together, before any vesicular property is imparted to the mass, render the most complete incorporation of the flour and water a matter of very easy accomplishment; and this being secured, it is evident that the gas which forms the vesicle, or sponge, when it is released, must be dispersed through the mass in a manner which no other method—fermentation not excepted—could accomplish. But besides the advantages of kneading the dough before the vesicle is formed, in the manner above mentioned, there is another, and perhaps a more important one, from what it is likely to effect by giving scope to the introduction of new materials into bread making,—and that is, I find that powerful machine-kneading, continued for several minutes, has the effect of imparting to the dough tenacity or toughness. In Messrs. Carr and Co.'s machine, at Carlisle, we have kneaded some wheaten dough for half an hour, and the result has been that the dough has been so tough, that it resembled birdlime, and it was with difficulty pulled to pieces with the hand. Other materials, such as rye, barley, &c. are affected in the same manner. So that by thus kneading, I am able to impart to dough made from materials which otherwise would not make light bread, from their wanting that quality in their gluten which is capable of holding or retaining, the same degree of lightness which no other method is capable of effecting. And I am sanguine of being able to make from rye, barley, oatmeal, and other wholesome and nutritious substances, bread as light and sweet as the finest wheaten bread. One reason why my process makes a bread so different from all other processes where fermentation is not followed is, that I am enabled to knead the bread to any extent without spoiling its vesicular property; whilst all other unfermented breads are merely *mixed*, not kneaded. The property thus imparted to my bread by kneading, renders it less dependent on being placed immediately in the oven. It certainly cannot *gain* by being allowed to stand after the dough is formed, but it bears well the necessary standing and waiting required for preparing the loaves for baking.

"There is one point which requires care in my process, and that is,—the *baking*: as the dough is excessively cold; first, because *cold* water is used in the process; and next, because of its sudden expansion on rising. It is thus placed in the oven some 40° Fahr. in temperature lower than the ordinary fermented bread. This, together with its slow springing until it reaches the boiling point, renders it essential that the *top* crust shall not be formed until the very last moment. Thus, I have been obliged to have ovens constructed which are heated through the bottom, and are furnished with the means of regulating the heat of the top, so that the bread is *cooked through the bottom*; and, just at the last, the top heat is put on and the top crust formed.

"With regard to the *gain* effected by saving the loss by fermentation, I may state what must be evident, that the weight of the dough is always exactly the sum of the weight of flour, water, and salt put into the mixing vessel; and that, in all our experiments at Carlisle, we invariably made 118 loaves from the same weight of flour which by fermentation made only 105 and 106. Our advantage in gain over fermentation can only be equal to the *loss* by fermentation. As there has been considerable difference of opinion among men of science with respect to the amount of this loss—some stating it to be as high as 17½ per cent., and others so low as 1 per cent.—I will here say a few words on the subject. Those who have stated the loss to be as high as 17½ per cent. have, in support of their position, pointed to the extra yield from the same flour of bread when made by non-fermentation, compared with that made by fermentation. Whilst those who have opposed this assertion, and stated the loss to be but 1 per cent. or little more, have declared the gain in weight to be simply a gain of extra water, and have based their calculations of loss on the destruction of

Digitized by Google

material caused by the generation of the necessary quantity of carbonic acid to render the bread light. Starting then with the assumption that light bread contains in bulk half solid matter and half aëriform, they have calculated that this quantity of aëriform matter is obtained by a destruction of but *one* per cent. of solid material. In this calculation the loss of carbonic acid, by its escape through the mass of dough during the process of fermentation and manufacture, does not appear to have been taken into account. All who have been in any way practically connected with bakeries well know how large this loss is, and how important it is that it should be taken into account, that our calculations may be correct.

"One of the strongest proofs that the escape of gas through ordinary soft bread dough is very large arises from the fact, that when biscuit dough, in which there is a mixture of fatty matter, is prepared by my process, about half the quantity of gas only is needed to obtain an equal amount of *lightness* with dough that is made of flour and water only, the fatty matter acting to prevent the escape of gas from the dough. Other matters will operate in a similar manner—boiled flour, for instance, added in small quantities. But the assumption that light bread is only half aëriform matter is altogether erroneous. Never before has there been so complete a method of testing what proportion the aëriform bears to the solid in light bread as that which my process affords. The mixing vessel at Messrs. Carr and Co.'s works, Carlisle, has an internal capacity of 10 bushels. When 3½ bushels of flour are put into this vessel, and formed into spongy bread dough, by my process, it is quite full. And when flour is mixed with water into paste, the paste measures rather less than half the bulk of the original dry flour. This will therefore represent about 1¾ bushels of *solid* matter expanded into 10 bushels of spongy dough, showing in the *dough* nearly 5 *parts aëriform* to 1 solid; and in all instances, if the baking of this dough has not been accomplished so as to secure the loaves to 'spring' to at least *double* their size in the oven, they have always come out heavy bread when compared with the ordinary fermented loaves. This gives the relative proportion of aëriform to solid in light bread at least as 10 to 1, and at once raises the loss by fermentation from 1 to 10 per cent., without taking into account the loss of gas by its passage through the mass of dough.

"Of the quality and properties of the bread manufactured by my process, there will shortly be ample means of judging. I may be allowed, however, here to state, what will be evident to all, that the absence of everything but flour, water, and salt, must render it absolutely pure;—that its sweetness cannot be equalled except by bread to which sweet materials are superadded;—that, unlike all other unfermented bread, it makes excellent toast; and, on account of its high absorbent power, it makes the most delicious sop puddings, &c., and also excellent poultice. Sop pudding and poultice made from this bread, however, differ somewhat from those made from fermented bread, in being somewhat richer or more glutinous. This arises from the fact of the gluten not having been changed, or rendered soluble, in the manner caused by fermentation; but that this is a good quality rather than a bad one is evident from the fact, that the richer and purer fermented bread is, the more glutinous are the sop, &c., made from it; and the poorer and more adulterated with alum it is, the freer the sop, &c., are of this quality."

Such then is Dr. Dauglish's plan, and it is impossible to deny that it possesses great ingenuity.

From the fact that, in all his experiments at Carlisle, Dr. Dauglish invariably made 118 loaves from the same weight of flour which, by fermentation, made only 105 or 106, to argue that the *gain over fermentation* can only be equal *to the loss by fermentation*, is to draw a somewhat hasty conclusion; for the gain may be, and is probably due, not to the preservation in the bread of what is generally lost by fermentation, but simply to a retention of water.

It is of course certain that the production of the porosity required in bread produced by the carbonic acid and alcohol evolved by fermentation, entails the loss of a portion of the valuable constituents of the flour, but the amount of that loss should not be estimated, I think, from the proportions which the aëriform bear to the solid matter of the loaf *after it is baked.*

In effect, the fermentation induced in bread differs from that produced at the distillery, in as much as, instead of the fermenting material being sheltered from the air by an atmosphere of carbonic acid, the dough is on the contrary thoroughly permeated by, and retains a considerable quantity of atmospheric air introduced into it by the kneading process, and owing to the presence of which, in fact, the acetous fermentation is carried on to a certain extent, within the dough, simultaneously with the alcoholic fermentations, so that even the 10 parts of aëriform matter to 1 of solid matter in a quartern loaf, are not altogether carbonic acid resulting from the fermentation, but are carbonic acid from that source mixed with the atmospheric air with which the

Digitized by Google

dough is permeated. On the other hand, the aëriform matter thus imprisoned in the dough, expands to at least twice its volume when exposed to the temperature of the oven, and accordingly the bread after breaking becomes as bulky again as the dough from which it was made, and this doubling of the volume being due to the expansion of the gases, and not to the fermentation, bears no proportion whatever to the amount of the sugar of the flour employed in the production of the alcohol and carbonic acid evolved. Moreover, as a quartern loaf, for example, measures about 9 inches by 6·5 inches by 5 inches, making a total of about 292 cubic inches, if we take nine-tenths of that to be aëriform matter, we have 262·8 inches as the aëriform cubic contents of the quartern loaf.

It is ascertained beyond doubt by numerous experiments, that genuine, properly manufactured new bread contains, on an average, 42·5 per cent. of water, and 57·5 of flour, and consequently a quartern loaf weighing really four pounds, would consist of 11,900 grains of water and 16,000 grains of solid matter, 422·5 grains of which are salt and inorganic matter, the rest, 15677·5 grains, being starch and gluten. Now a quartern loaf measuring about 9 × 6·5 × 5 inches gives a total of 292 cubic inches. Assuming with Dr. Dauglish, nine-tenths of that to be aëriform matter, we have 262·8 inches as the aëriform cubic contents of a quartern loaf, but as the gases expanded in the dough to double their volume during its being baked into a loaf, we must divide by 2 the 262·8 inches above alluded to, which gives 131 4 as the number of cubic inches of aëriform matter contained in the dough before it went into the oven. Again, assuming with Dr. Dauglish that these 131·4 cubic inches consist altogether of carbonic acid resulting from the fermentation of the flour, they would represent in weight only 62 grains of that gas, and as 1 equivalent = 198 of sugar produces 4 equivalents = 88 of carbonic acid, it follows that, at most, about 140 grains of sugar or solid matter out of the 15677·5 of flour in the quartern loaf would have disappeared, which loss is less than 1 per cent., from which, however, it is necessary to make a considerable reduction, since a large quantity of air is mixed with that carbonic acid, and expanded with it in the oven. Unless, therefore, it can be satisfactorily proved that the unfermented bread manufactured by Dr. Dauglish's process is more nutritious, weight for weight, or more digestible, or possesses qualities which fermented bread has not, or is sold at a reduced price proportionate to the quantity of water thus locked up and passed off for bread, the benefits and advantages will be all on the manufacturer's side, but the purchasers of the unfermented bread will make but a poor bargain of it.

Of all the operations connected with the manufacture of bread, the most laborious, and that which calls most loudly for reform, is that of kneading. The process is usually carried on in some dark corner of a cellar, where the temperature is seldom less than 60° F., and frequently more; by a man, stripped naked down to the waist, and painfully engaged in extricating his fingers from a gluey mass into which he furiously plunges alternately his clenched fists, heavily breathing as he, struggling, repeatedly lifts up the bulky and tenacious mass in his powerful arms, and with effort flings it down again with a groan fetched from the innermost recesses of his chest, and which almost sounds like an imprecation.

We know, on very good and unexceptionable authority, that a certain large bakery on the borders of a canal actually pumped the water necessary for making the dough directly and at once from the canal, and this from a point exactly contiguous to the dischargings of the cesspool of that bakery? And let us not imagine that this is a solitary instance of horrible filth. The following memoranda recorded by Dr. Wm. A. Guy, in his admirable lecture on "The Evils of Night-work and Long Hours of Labour," delivered on Thursday, July 6, 1848, at the Mechanics' Institution, Southampton Buildings, will serve to illustrate the condition of the bakehouses:—

1. Underground, two ovens, no daylight, no ventilation, very hot and sulphurous.
2. Underground, no daylight, two ovens, very hot and sulphurous, low ceiling, no ventilation but what comes from the doors. Very large business.
3. Underground, no daylight, often flooded, very bad smells, overrun with rats, no ventilation.

After mentioning several other establishments in the same, or even in a worse, condition than those just enumerated, Dr. Guy adds—

"The statements comprised in the foregoing memoranda are in conformity with my own observations. Many of the basements in which the business of baking are carried on are certainly in a state to require the assistance of the Commissioners of Sewers, and to invite the attention of the promoters of sanitary reform."

If we reflect that bread, like all porous substances, readily absorbs the air that surrounds it, and that, even under the best conditions, it should never, on that account, be kept in confined places, what must be the state of the bread manufactured

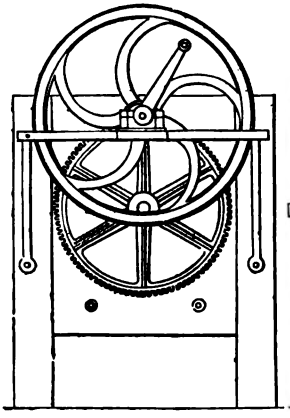
Digitized by Google

in such a villanous manner, and with a slovenliness greater than it is possible for our imagination to conceive? What can prove better the necessity of Government supervision than such a fact? The heart sickens at the revolting thought, but after all there is really but little difference between the particular case of the bakery on the border of a canal above alluded to, and the mode of kneading generally pursued, and to which we daily submit.

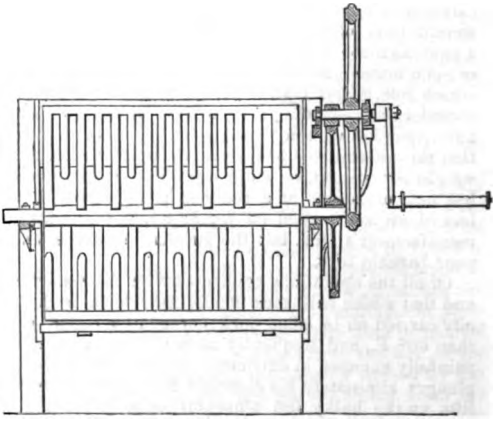
In the sitting of the Institute of France, on the 23rd of January, 1850, the late M. Arago presented and recommended to the Académie the kneading and baking apparatus of M. Rolland, then a humble baker of the 12th Arrondissement, which, it would appear, fulfils all the conditions of perfect kneading and baking.

"The kneading machine (*pétrin mécanique*) of M. Rolland," says Arago, "is extremely simple, and can be easily worked, when under a full charge, by a young man from 15 to 20 years old: the necessity for horse labour or steam power may thus be obviated. The machine (*figs.* 239 to 242) consists of a horizontal axis traversing a trough containing all the dough requisite for one baking batch, and upon which axis a system of curvilinear blades, alternately long and short, are placed in such a manner that, while revolving, they describe two quarters of cylindrical surfaces with contrary curves, so that the convexity of one of these surfaces, and the concavity of the other, is turned towards the bottom of the trough. The axis has a fly wheel, and is set in motion by two small cog-wheels connected with the handle, as represented in the following figures:—

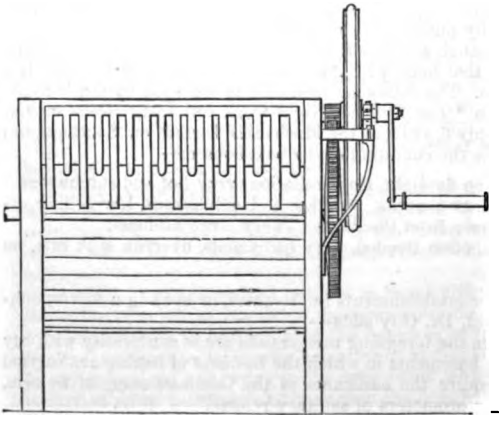
239



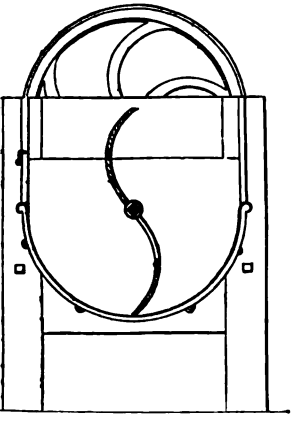
240



241



242



The action of the kneading machine is both easy and efficacious. In 20, and if necessary in 15, or even 10 minutes, a sack of flour may be converted into a perfectly

Digitized by Google

homogeneous and aërated dough, without either lumps or clods, and altogether superior to any dough than could be obtained by manual kneading. The time required in kneading varies according to the greater or less density of dough required; and the quantity of dough manufactured in that space of time varies, of course, also with the dimensions of the kneading-trough; for instance, in the trough provided with 16 blades, one sack and a half of flour can be kneaded at once; in that of 14 blades one sack, and in that of 12 blades two-thirds of a sack.

M. Rolland gives the following instructions for the use of the machine, in order to impart to the dough the qualities produced by the operations known in France under the names of *frasage*, *contrefrasage*, and *soufflage*, which we shall presently describe, and to which the bread manufactured in that country mainly owes, in the words of Dr. Ure, "a flavour, colour, and texture, never yet equalled in London."

The necessary quantity of leaven or yeast is first diluted with the proper quantity of water, as described before; and in order to effect the mixture, the crank should be made to perform 50 revolutions alternately from right to left.—*Frasage* is the first mixture of the flour with the water. The flour is simply poured into the kneading-trough, or, better still, when convenience permits it, it is let down from a room above through a linen hose, which may be shut by folding it up at the extremity.

Three-fourths only of the flour should at first be put into the trough; the first revolutions of the kneader should be rather rapid, but during the remainder of the operation the turning should be at the rate of about two or three revolutions a minute, according to the density of the dough to be prepared. The dough thereby having time to be well drawn out between the blades, and to drop to the bottom of the trough. From 24 to 36 revolutions of the crank will generally be sufficient; but in order to obtain the dough in the condition which the *frasage* would give it in the usual way, it will be necessary to make about 250 revolutions of the crank alternately from right to left, about the same number of turns.

Contrefrasage is the completion of the process of mixing; and, in order to perform that operation, the last fourth part of the flour must now be added, the crank turned 150 revolutions, to wit, 75 turns rather slowly, alternately from right to left, and the remainder at the rate of speed above mentioned.

The operation of *Soufflage* consists in introducing and retaining air in the paste. To effect this, the kneader should be made to perform, during nearly the whole time occupied in the operation, an almost continual motion backwards and forwards, by which means the dough is shifted from place to place; five revolutions being made to the right, and five to the left, alternately, taking care to accelerate the speed a little at the moment of reversing the direction of the revolving blades.

All these operations are accomplished in twenty or twenty-five minutes.

Of course, the reader should not imagine that these numbers must be strictly followed, they are given merely as a guide indicative of the *modus operandi*.

The kneading being completed, the dough is left to rest for some time, and then divided into lumps, of a proper weight, for each loaf. The workman takes one of these lumps in each hand, rolls them out, dusts them over with a little flour, and puts each of them separate in its *panneton*; he proceeds with the rest of the dough in the same manner, and leaves all the lumps to swell, which, if the flour have been of good quality, will take place at a uniform rate. They are then fit for baking, which operation will be described presently.

Another kneading trough, said to be very effectual, is that for which Mr. Edwin Clayton obtained a patent in August, 1830. It consists of a rotatory kneading trough, or rather barrel, mounted in bearings with a hollow axle, and of an interior frame of cast iron made to revolve by a solid axle which passes through the hollow one; in the frame there are cutters diagonally placed for kneading the dough. The revolving frame and its barrel are made to turn in contrary directions, so as greatly to save time and equalise the operation. This double action represents kneading by the two hands, in which the dough is inverted from time to time, torn asunder, and reunited in every different form. The mechanism will be readily understood from the following description.

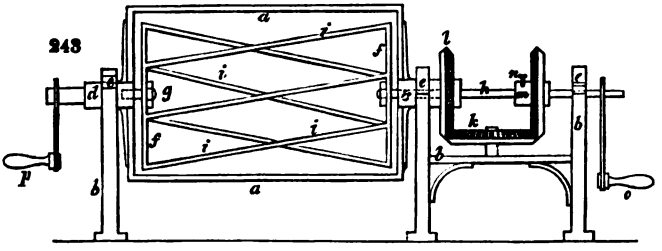
Fig. 243 exhibits a front elevation of a rotatory kneading trough, constructed according to improvements specified by the patentee, the barrel being shown in section; *a* is the barrel, into which the several ingredients, consisting of flour, water, and yeast, are put, which barrel is mounted in the frame-work *b*, with hollow axles *c* and *d*, which hollow axles turn in suitable bearings at *e*; *f* is the revolving frame which is mounted in the interior of the barrel *a*, by axles *g* and *h*. The ends of this revolving frame are fastened or braced together by means of the oblique cutters or braces *i*, which act upon the dough when the machine is put in motion, and thus cause the operation of kneading.

Either the barrel may be made to revolve without the rotatory frame, or the rota-

Digitized by Google

tory frame without the barrel, or both may be made to revolve together, but in opposite ways. These several motions may be obtained by means of the gear-work, shown at *k*, *l*, and *m*, as will be presently described.

243



If it be desired to have the revolving motion of the barrel and rotatory frame together, but in contrary directions, that motion may be obtained by fastening the hollow axle of the wheel *m*, by means of a screw *n*, to the axle *h* of the rotatory frame *f* tight, so as they will revolve together, the other wheels *k* and *l* being used for the purpose of reversing the motion of the barrel. It will then be found that by turning the handle *o*, the two motions will be obtained.
